Capsids of *Caudovirales* are built as precursor procapsids, into which the phage genome is later packed. Procapsids are initially assembled from several types of components: a portal complex, which will connect the capsid to the tail, a major capsid protein, a scaffolding protein (which may be a separate protein or may be a disposable (removable) part of the major capsid protein). Phages may also utilize decoration or stabilization proteins, but these are not part of the procapsid and add to and stabilize the capsid only after the genome is packed inside. The number of capsid protein subunits needed for assembly is equal to $\sim 60 \times T$ subunits, where T is the triangulation number listed in [Table 1](#) (or, for phages with elongated capsids, $\sim 30 \times (T + Q)$ subunits, where T and Q are specified in [Table 1](#)). One vertex of a phage capsid is occupied by the portal complex, so the number of capsid proteins will be 5 less than calculated by the simplified formulae. So for a $T = 7$ virus, such as λ , $420 - 5 = 415$ copies are needed. Some phages, including phage T4 and relatives, also make a specialized minor capsid protein that forms the pentameric vertices of the icosahedral capsids, but most do not. Capsid assembly in *Caudovirales* begins with the completion of the assembly initiator complex, the portal or connector, composed of 12 copies of the portal protein, which occupies one of the 12 icosahedral vertices of the capsid. The major capsid protein(s), together with hundreds of copies of the scaffolding protein co-assemble onto the initiator to produce a complete shell with the scaffolding protein on the inside. After assembly is complete, the scaffolding protein is expelled intact or digested by a special protease that is also incorporated into the procapsid. Procapsids appear spherical and usually have a smaller diameter than mature capsids. When DNA is packaged into the procapsid, the capsid usually expands and changes shape, transforming into the typical angular, icosahedral shape of mature capsids. If present, decoration proteins add to the outside of the capsid after it expands and help

to stabilize the structure. Once DNA is packaged, the capsid is made ready to join to a tail by the addition of proteins that bind to the portal.

Lysis

Lysis of a typical *Caudovirales* host usually requires the breaching of the bacterial envelope, which usually requires separate factors for each of the envelope's layers. For example, in gram negative hosts, holins are used to breach the inner membrane, a lysozyme or endolysin is used to break down the peptidoglycan intermediate layer, and spannins are used to breach the outer membrane. The endolysin is a soluble enzyme with the capacity to break the bonds holding the host cell wall together. The endolysin molecules accumulate within the host cytoplasm during the late stages of infection, but are unable to attack the cell wall because they are sequestered within the cytoplasmic membrane. Holin proteins allow the endolysin to get across the cytoplasmic membrane by forming holes in the inner membrane. Holins are synthesized and inserted into the membrane in a form that does not form holes at first. As the bacteriophage infection proceeds, the holins accumulate in the membrane until a predetermined time at which they suddenly and catastrophically induce membrane breakdown. The membrane holes produced by holins allow the endolysin molecules to attack the bacterial cell wall, causing rapid cell lysis and releasing the progeny *Caudovirales* from the cell. Spannins usually work as a pair (one each for the inner and outer membranes) and appear to disrupt the outer membrane by mediating fusions between the inner and outer membranes.

Genomes and Genomics

Chromosome Diversity and Replication

The chromosomes that are packaged into the capsids of the *Caudovirales* are linear dsDNA. *Caudovirales* virions always contain an entire genome or, alternatively more than an entire genome to ensure that a complete genome is packaged into each and that every particle can initiate an infection. To achieve this, a site-specific mechanism may be used, in which DNA packaging begins and ends at defined sites that are recognized by the packaging machinery to create exactly unit genome length DNA chromosomes. Alternatively, the amount of virion DNA may be regulated by a head-full packaging mechanism which fills a capsid that has the capacity to hold slightly more than one genome's worth of DNA. The head-full-packaged chromosomes have the same sequence at each end and are said to be terminally redundant.

After injection, the phage genomes often rearrange to form a circular chromosome that is the primary replicative form of the genome of many dsDNA phages, however, many other phages replicate without forming such DNA circles. *Caudovirales* chromosome replication often takes place bi-directionally from a single origin, but more complex replication schemes and multiple replication origins have also been observed. Late in infection, most phages switch to a mode of replication that produces DNA concatemers, or long strings of genome copies joined end to end, either by a rolling circle mode of replication from circular chromosomes, or by recombination between multiple overlapping genome copies. Such DNA concatemers, whether linear or branched, are the forms of the genome that are the usual substrate for DNA packaging for both head-full and site specific mechanisms. When it does occur, circularization of the phage chromosome takes place via one of two mechanisms. The first is by the annealing of complementary single-stranded DNA sticky ends left by the packaging enzymes, in the cases where the packaged chromosomes have defined endpoints. The second is by a recombination-like mechanism that joins the complementary regions of the overlapping, terminally redundant chromosome ends to form circular DNA molecules. Circular chromosomes are the most common form for bacterial chromosomes, but some bacteria also have linear chromosomes, and a small subset of the *Caudovirales* also form linear chromosomes that replicate as linear plasmids when in their lysogenic form.

Diversity in Genome Size and Organization

The genomes of *Caudovirales* range in size from ~20,000 base pairs in phage ϕ 29, to ~170,000 base pairs in phage T4, and up to ~500,000 base pairs in other known examples. The smaller phages have proportionally fewer genes than the large phages, but are functional and successful phages none the less. Given this wide range of sizes and diversity of the *Caudovirales*, it is not surprising that there is not a common conserved genome structure for this order of viruses. Within a genus of phages there is often a common genetic structure, but within and across families there is often little resemblance in genome organization. There are notable exceptions to these generalizations, for example, the genus "P22-like viruses" and the genus " λ -like viruses" have rather closely related genomes.

Common Themes in Genome Structure

Despite the differences mentioned, there are many common general features in *Caudovirales* genomes. The genes for the structural proteins, such as those for capsids, tails, or tail fibers, tend to be found clustered together, and within these clusters, the genes that encode proteins that physically interact with each other also tend to be grouped together. For example, the capsid protein genes for

the portal, the scaffolding protein and the major capsid protein usually occur together and in the order listed. Sets of late genes are often grouped together in clusters and, in some cases, the entire set of structural genes are grouped together in clusters and transcribed together from a single promoter, as is the case for phage λ .

Horizontal Exchange of Genes is Widespread

A large number of complete bacteriophage genomes have been fully sequenced, and thousands of these have been deposited in GenBank and other databases. In addition, there are also many temperate phages residing in the genomes of bacterial chromosomes deposited in GenBank, some defective (or cryptic), some complete and able to form viable phage. Analyses of the sequences of these genomes have shown that many of the genes of the *Caudovirales* have highly similar counterparts in other genomes and in many cases the similarity can be inferred to be truly homologous. An important conclusion of these analyses is that there is extensive horizontal exchange of genes between phages that are not within the same species or genus or order. It appears that genetic exchange between phages by both homologous and non-homologous recombination mechanisms is widespread and that many phages are mosaic combinations of genes found elsewhere. Many of the homologous genes are within the *Caudovirales*, but some are from outside this group. In some cases, large modules of genes in a pair of phages are closely related, for example, the head genes of phage HK97 (*Siphoviridae*) and phage SfV (*Myoviridae*), despite belonging to different taxonomic groups. In other cases, a single phage tail fiber encoding gene in one phage may contain several distinct regions of homology with several other different phages.

Common Ancestry

The exact nature of the evolutionary relationships among phages and how it relates to phage taxonomy is a controversial subject, but at the level of individual protein coding genes, it is fairly certain that proteins with a high degree of sequence similarity in analogous proteins almost certainly share a common evolutionary ancestor. The power and utility of bioinformatics to tease out weak (sequence) similarities between distantly related proteins gives the evolutionary scientist powerful tools to detect relationships that escape casual examination. However, the reliance on sequence similarity matches to detect homologous relationships breaks down when homologous proteins have diverged so far that sequence similarity is undetectable. A notable case is that of the major capsid proteins of bacteriophages and other viruses. The 3-dimensional structure and protein fold of the major capsid protein of phage HK97 was determined to high resolution by x-ray crystallography. Sensitive bioinformatic techniques were able to detect weak sequence similarities between the HK97 capsid protein sequence and the capsid proteins of a large number of other *Caudovirales*, suggesting that the HK97 capsid protein fold is quite common. Subsequently, the determination of the protein folds of phages T4 (*Myoviridae*), P22, ϕ 29, and epsilon 15 (*Podoviridae*) and many other phages, by structural methods has shown that all of these phages also have the same protein fold as HK97, despite the lack of any detectable sequence similarity. This structural similarity also extends to the capsid proteins of the Herpesviruses, which use a variant of the HK97 fold for their the floor domains of their much larger major capsid proteins and also have a portal protein with fold similar to their bacteriophage homologs.

Glossary

Adsorption Binding of phage particles to the receptor on the bacterial cell surface.

Atomic force microscopy (AFM) High resolution scanning microscope with a laser-controlled cantilever.

Conjugation Sexual contact of bacteria to exchange genetic information from the donor to the recipient cell involving a F-pilus of the donor cell.

Extremophilic bacteria Bacteria that live at high (thermophilic) or very low (psychrophilic) temperatures.

Filamentous Morphology of the phage that defines the *Inoviridae*. At the proximal end 5 copies of the gp3 adsorb to the tip of a F-pilus of the host cell.

Membrane insertion Newly synthesized proteins that are incorporated into the membrane before their assembly into the phage particle.

Morphogenetic signal Sequence on the viral DNA that is responsible to initiate DNA the packaging reaction.

Pathogenicity Factors encoded by the viral DNA that are toxic for the human organism the bacterial host colonizes.

Rolling circle replication Continuous replication mode to generate the single stranded phage DNA to be packaged to the progeny particles.

Introduction

The first filamentous phage was isolated 60 years ago in Germany, when Hartmut Hoffmann-Berling took a sample from the backyard of a cattle farm close to Heidelberg. In the lab, he tested the sample for plaque formation on *Escherichia coli* Hfr. Since the selected phage contained DNA and appeared male-specific it was named “fd”. Nearly at the same time, Tim Loeb at the Rockefeller institute isolated the male-specific “f1” phage and Hans-Peter Hofschneider in Munich phage M13, who also showed its filamentous morphology with the electron microscope. The “M” in M13 stands for Munich, and it was Hofschneider’s 13th isolate. Today we know that the three phages, fd, f1 and M13, are nearly identical in their DNA sequence and therefore can be considered as an identical phage (termed Pf phage). The fd genome was one of the first to get determined with 6408 bases. The advantage of single-stranded DNA (ssDNA) for the in vitro replication reaction helped to determine the first sequences in general. Because of this, any DNA was ligated into the M13 genome and after transfection the phage was isolated to purify the ssDNA for sequencing. At this time, M13 was the common vehicle for DNA sequencing.

In the early work of Hoffmann-Berling it was recognized that the fd phage was “liberated” from cells without lysis, in an unknown “new phage liberation mechanism”. In addition, the first studies of their morphogenesis revealed no visible cytoplasmic intermediate structures as had been observed with many other phages. Experiments by Rolf Knippers to assemble the phage *in vitro* by mixing the ssDNA with the major coat protein gp8 were unsuccessful. Instead, as we know today, the phage is assembled in the membrane during its secretion and requires the membrane to coat the ssDNA in an ordered secretion process and involving a motor protein complex in the membrane. The assembly and secretion of the phage requires the catalytic proteins gp1, gp4, gp11 and thioredoxin of the host.

The filamentous phage again became famous when Johnny Mekalanos discovered that the cholera toxin gene was embedded in an integrated phage CTX-(ϕ) genome. Following this observation, many more genome-integrated cryptic filamentous phages were detected in *Vibrio cholerae*. In fact, there might be a huge number of integrated filamentous phages in the metagenome which are not yet identified. Virulent filamentous phage have been found in *Pseudomonas* (Pf1 to Pf7), *Xanthomonas* (Xf, Cf, Lf, Xv2), *Salmonella* (Lineavirus lke), *Ralstonia* (*Habenivirus* RSM1 to 3, RSS1, RS603), *Vibrio* (*Fibrovirus* fs1, *Saetivirus* fs2), and in *Spiroplasma* (*Plectovirus* 1-C74, *Vesperitiliovirus* 1-R8A2B) and recently also in *Thermus thermophilus*.

Phylogenetic studies show that gene 1 is the most conserved among the known filamentous phage genes and can be taken as a basis for a phylogenetic tree. This analysis suggests that there are several distinct clades, where the *Inoviridae* group together with *Lineaviridae* and *Saetiviridae* are distinct from the known *Vibrio* and *Pseudomonas* phages.

Similar in structure but genetically unrelated to the filamentous phage are the helical phages that were found in archaea. The *Lipothrixviridae* and *Rudiviridae* infect *Crenarchaea* and are 400–2200 nm long tubular particles with a diameter of about 20 nm. They contain linear dsDNA of 16–60 kbp that is packed with a helical capsid protein. Another helical archaeovirus, termed *Clavavirus* has recently been discovered that contains a circular dsDNA of 5.3 kbp. No sequence homology has been found in the current data base. The diameter of the virus is 16 nm with a length of only 143 nm.

Biotopes: Prolific, Temperate and Pathogenic

The discovery of filamentous phages was delayed and still is hampered by a crucial technical step to remove larger debris including bacterial cells from aqueous samples by employing porous membranes or filters. Due to this step, spheroidal particles are more likely obtained than elongated ones, thus leading to a removal of filamentous phages from most samples. Therefore, it was estimated that filamentous phage representatives are by numbers only about 5% of those of spherical or head-and-tail phages. In contrast to this estimate, a recent publication in the field of (meta-) genomic sequencing indicated that there are many more filamentous phages than previously thought. According to the study, the currently described 56 members of the *Inoviridae* family represent only a small fraction of a highly diverse group that is proposed to even extend to the archaea kingdom. Astonishingly, *Inovirus* sequences have been identified in 35% of the metagenome sequences available until 2019. About 6% of the annotated genomes from bacteria and archaea contain filamentous phage genes. These sequences cover only the ones that are integrated into the host genome. Therefore, it can be assumed that many more filamentous phages exist often in a plasmid like state, as bacterial viruses are found as an episome or chromosomally integrated.

Not only their DNA, but the filamentous phage particles themselves have been discovered in all biotopes on the planet. Most of the ecosystems where filamentous phages can be found are moderate in nature and are inhabited by mesophiles, i.e., environments with “normal” temperatures and pH, such as the gut of mammals including humans, where they infect *proteobacteria*, including *enterobacteria* (an estimated 90%). Surprising is the partnership that some filamentous phages have entered. To the benefit of the phage which uses the cellular replication machinery, the bacterial host itself has been shown in some cases to obtain an evolutionary advantage by being infected with the virus. Many of the filamentous viruses have a parasitic lifestyle, living on the expense of the host cell. However, thus in some cases a mutualistic relationship is discussed as filamentous virus was found to influence certain host characteristics to the benefit of both, the bacterium and the phage. The most prominent example is the bacteriophage CTX- ϕ that infects *Vibrio cholerae*, and delivers the genes for the cholera toxin to a comparably harmless bacterium. Once integrated into the genome, cholera toxin A and B are produced, leading to a destruction of the mucosal membranes resulting in a high influx of water, causing diarrhea. Release of the phage (excision) is triggered by a drop in pH, as found in the intestines of a human host, thus allowing other bacteria to be infected by the phage, turning the infected bacteria into highly virulent ones, in a process called phage conversion, resulting in a so-called toxigenic *Vibrio* strain. It is thought that the cholera toxin genes have been acquired by an evolutionary predecessor of the CTX- ϕ phage, giving the virus a unique advantage as the spreading of a highly virulent bacterial host is also beneficial for the phage. CTX- ϕ is not the only *Vibrio* phage; there is a vast variety of phages most of which are genome-integrated such as VGJ- ϕ which integrates into the same sites as CTX- ϕ . Interesting is the occurrence of prophages with incomplete genomes, also known as satellite phages. These phages piggyback on some of the genes of their relatives, leading to the formation of so-called mosaic phages. An example is RS1 which has been reported to use the morphogenesis protein gp1 of CTX- ϕ in order to form phage particles.

Yersinia pestis is another example where a filamentous phage contributes to the pathogenicity of a bacterium. *Y. pestis* evolved from the enteropathogen *Yersinia pseudotuberculosis* about three millennia ago and became infected by the filamentous phage Ypf-Phi, which remained an extrachromosomal element in many lineages. The *Y. pestis* strain that contained the phage integrated into the host genome, caused the third plague epidemic. This major bubonic plague pandemic began in China in 1855 and spread to all inhabited continents, killing more than 12 million in China and India alone. Interestingly, the phage Ypf- ϕ infects *Y. pestis* but also *Y. pseudotuberculosis* and *Yersinia enterocolitica*. In addition, the transduction is also expanded to *E. coli* strains. In contrast to being genome integrated in *Y. enterocolitica*, the phage exists as an extrachromosomal plasmid in *Y. pseudotuberculosis* and in *E. coli*. The presence of the phage confers better colonization abilities of the host in mammalian tissues. While Ypf- ϕ is not a major virulence factor, it confers a higher fitness and an increase in pathogenicity to the bacterium, albeit modest.

Some commensal bacteria become opportunistic pathogens upon the genetic acquisition of virulence factors. *E. coli* is no exception to this phenomenon where the enterobacterium causes diarrhea, urinary tract infections but also sepsis, and meningitis. For example, the *E. coli* strain O18:K1:H7 is one of the leading causes of neonatal meningitis and cystitis in North America. The serotype CO92 carries a genetic element called CUS-1 which was identified to be a filamentous prophage. The genome of the phage is almost identical to CUS-2 found in *Y. pestis* biovar orientalis. Both contain a gene called *puvA* which, when destroyed, affects the ability of *E. coli* K1 strains to systemically propagate or even survive *in vivo*, indicating a role in pathogenesis. The gene is flanked by several other genes that show high similarity to those coding for coat proteins and proteins crucial for morphogenesis of other filamentous phages. Filamentous phage particles much like M13 were detected in the supernatant of cultures from both, *E. coli* K1 as well as *Y. pestis* biovar orientalis CO92 cells, later called CUS- ϕ .

Another filamentous phage, MDA Φ , which infects *Neisseria meningitidis*, has been implicated to have a contribution to the virulence of the host when the virus is in a prophage state. While it was shown that the presence of the phage has no influence on virulence during the bloodstream stage of *N. meningitidis*, it has been demonstrated that phage-infected bacteria are more efficient in colonizing host epithelial cells during the progression of the disease.

While being directly responsible for the pathogenicity of their host, filamentous phages can affect the immune system of a human directly, when infected by bacteria harboring such a virus. In case of the *Pseudomonas aeruginosa* phage Pf, the co-existence of the phage in their host impacted the healing process negatively, leading to chronic, badly and slow-healing wounds. In the mouse model, 50 times fewer *Pseudomonas* cells were required to cause a wound infection, when comparing phage-infected to non-infected cells. Also, the rate of morbidity was increased when mice were infected with *Pseudomonas* harboring phage. Surprisingly, the effects were caused not by increased virulence of the bacteria but by the immune response of the mammalian host. The uptake

of phage particles by macrophages caused among other cellular reactions, a Toll-like receptor response, mediated by the mRNA which is transcribed from the phage DNA, as well as to the inhibition of phagocytosis, suggesting that phage can play a direct pathogenic role in the infection process.

Filamentous phages can be found on plants, in the soil, on food products and in lakes, rivers and the sea. Also in extreme environments where extremophilic bacteria are present, filamentous phages have been discovered. Examples are volcanic hot springs that are found all over the world, including in Japan, where the phage (ϕ)-OH3 has been discovered together with its host *Thermus thermophilus*. The conditions where host and virus thrive are around 70°C with an almost neutral pH and low osmolarity. The stability and infectivity of the filamentous phage reflect this environment, as a higher temperature, high salt or low and high pH are detrimental and lead to denaturation and inactivation of the virus. While it is not known whether the phage confers any benefit to the host, or is purely parasitic, the existence of a thermostable phage might possibly allow nanotechnological applications under elevated temperatures.

On the other temperature extreme, cold-adapted microorganisms were also found to harbor filamentous phages. A psychrophilic bacterium from the *Pseudoalteromonas* group which thrives in the cold waters and in the ice of the arctic, can be infected by a filamentous phage called f327. Prokaryotes in the arctic ice and water are exposed to very low temperatures and large fluctuations in nutrient levels, salt and gas concentrations, as well as in pH. Interestingly, approximately 50% of the species living in permanent arctic ice belong to the genus *Pseudoalteromonas* of which more than 30% were found to contain filamentous phage genes. As one would expect from a parasite, phage infection resulted in slower growth rates and decreased final cell density. In addition, infected bacteria were also less tolerant towards changes in salinity or higher hydrogen peroxide concentrations compared to uninfected cells. Surprisingly, infected bacteria showed a much higher mobility, contrasting the negative impacts on cell viability mentioned above. Possibly, the increased mobility allows to reach nutrient enriched environments faster, e.g., when released from the ice at higher temperatures. While being psychrophilic, *Shewanella piezophila* is also a piezophile, i.e., a pressure-loving (or -tolerant) bacterium which lives on deep ocean floor, with optimal growth at a pressure of 20 MPa and a temperature of 20°C. The *S. piezophila* strain WP3 has been found to contain a genome-integrated filamentous phage, called SW1. SW1 is significantly induced at cold temperatures around 4°C, the typical temperature in the deep sea. The presence of the phage strongly impacts the expression of almost 50 host genes, many of them involved in flagella production. Interestingly, the phage does not influence the swimming motility of the host, while uninfected cells exhibit an increase in swarming motility at 4°C. Because motility is energetically expensive for cells, it is thought that the phage reduces this energetic cost by suppressing flagella genes and thus increases chance of survival of the host.

While the above-mentioned hosts are all Gram-negative bacteria, filamentous phage-like particles have also been observed to infect *Clostridium acetobutylicum*, a Gram-positive. So far, only one filamentous phage which infects a Gram-positive bacterium has been characterized in detail with regards to genome and proteins. The phage B5 uses *Propionibacterium freudenreichii* as a host to multiply, which is an important microbial component during the maturation of certain cheeses, in particular Emmental, where the carbon dioxide is responsible for forming the characteristic large holes. In contrast to contaminations, especially lytic phages can cause problems in industrial food processes where microorganisms are involved. However, B5 infection does not negatively influence the product. Whether or not this phage changes any pathways in the bacterial host, is currently not known.

Until today, no filamentous phages have been discovered that infect the third kingdom next to eukarya and bacteria, the archaea. However, a recently published metagenomic study revealed sequences of Inovirus-like genes with archaeal genomes that show highly conserved sequences of filamentous phages. In addition, a circular plasmid like episome of a filamentous virus has been isolated from *Methanobolus profundus*. The discovery of filamentous viruses in archaea is fascinating from an evolutionary perspective, as none of the currently characterized viruses infecting archaea are related to those of bacteria. Finding *Inovirus* genomes in both, archaea and bacteria, could be explained by the idea that this family existed very early on with a virus infecting a common ancestor. This conclusion is supported by the fact that the archaeal viruses display a high genetic diversity and lack strong similarity to bacterial phages, thus are likely not to result from a recent genomic exchange.

Structure of Filamentous Phages

Filamentous phages are structurally very different from other phages that usually have head and tail. Instead, they are long flexible filaments with two different ends, the base end which adsorbs to the host and the tip which is the end that leaves the host cell first during the secretion event. Based on early fiber diffraction methods, the filamentous phages were divided into two structural classes, where M13, f1 and fd are members of class 1 on which this review is focused. The fiber diffraction and other spectroscopic techniques showed the dimensions of the phage as a rod of about 890 Å in length and with a 6 Å diameter. The phage coat consists of an interdigitated helical arrangement of about 2750 copies of the major coat protein gp8. The slightly curved α -helical proteins cover the ssDNA with an about 20° tilt along the helical axis of the phage particle. The ssDNA is packed as two individual antiparallel strands within the protein tube where the phosphodiester backbone of the DNA may be electrostatically connected to the positively charged residues at the C-terminal of gp8. The helical arrangement of the coat proteins describe a C₅S₂ symmetry which states that 5 proteins start at the same time leading to a five-fold rotation axis. The coat proteins overlap such that the negatively charged N-terminal regions are exposed on the outside of the particle and the coat actually consists of two α -helical layers.

The two ends of the phage consist of the minor coat proteins. The base of the phage which is used to adsorb on the host cell is made of five copies each of gp3 and gp6. The two proteins form a defined structure visible as knobs with a diameter of about 50 Å

on the phage particles. The tip of the phage is formed by two small hydrophobic proteins gp7 and gp9, also with about five copies each. These two proteins are bound to the intergenic region of the ssDNA and initiate the packaging event.

Infection Process

The filamentous phages M13, fd and f1 are male-specific and infect only bacteria that have a F plasmid encoding the F-pilus. The central D2 domain of the “attachment protein” gp3 interacts with the tip of the F-pilus whereas the C-terminal D3 domain of gp3 is anchored to the phage capsid. The binding of the phage induces a retraction of the pilus similar as the binding of a recipient female cell does. The retraction brings the adsorbed phage close to the outer membrane surface and possibly also into the periplasm where it interacts with the TolQRA, an inner membrane protein complex with two large periplasmic domains. However, it is not known how the infecting phage actually crosses the outer membrane, but this might occur together with the F-pilus retraction process. In the periplasm, the C-terminal domain of TolA interacts with the N-terminal D1 domain of gp3. This binding is thought to trigger a conformational change in the C-terminal domain of gp3 and supports the insertion of gp3 into the inner membrane, possibly with help from TolQRA. Since the Tol complex is anchored in the inner membrane and spans the periplasm, it might offer a path for the infecting phage from the outer to the inner membrane. There, the phage particle is dissociated and the coat proteins partition into the inner membrane. In the inner membrane, it is discussed that the 5 copies of gp3 form a kind of DNA channel, possibly together with TolR, that allows the single stranded DNA to enter the bacterial cytoplasm.

Replication by the Rolling Circle Mechanism

Soon after the infecting phage DNA has entered the cytoplasm of the host it is a target of the DNA polymerase III which converts the single stranded DNA into a double strand. First, *E. coli* RNA polymerase binds to the intragenic region between *gene 4* and *gene 2* (b 5484–5987) to synthesize a short 30 base primer starting from base 5756. The primer is then extended with deoxyribonucleotides by DNA polymerase III and the RNA primer is replaced by deoxynucleotides catalyzed by DNA polymerase I of *E. coli*. DNA ligase of the host seals the ends of the double stranded DNA into a closed circle, termed replicative form RF I. This first stage involves no viral protein and the generation of the parental RF I is independent on the translation and expression of phage proteins.

DNA replication is then initiated by gp2, a soluble globular protein of 46 kDa. It has an endonucleolytic activity, attacks the parental RF DNA at a specific site and cleaves the (+) strand between the bases 5781 and 5782 in the intragenic region. Most likely, gp2 recognizes two hairpin structures (5692–5791) in the (+) strand and provides a free 5' end (RF II). In the early phase of infection *E. coli* polymerase III replicates the circular RF to about 100 copies per cell. Later in infection, the polymerization of the (–) strand is prevented by binding gp5, a single strand binding protein. As a result of this “rolling circle” only (+) strands decorated with gp5 are generated in the cells. Besides generating the endonucleolytic cut, gp2 has a second function in producing unit length ssDNA and sealing the 5' and 3' ends of the ssDNA-gp5 complex together to a closed circular DNA molecule. It is unknown whether also gp10 is involved in this process, since in the absence of gp10 the proliferation of phage is greatly reduced.

The ssDNA-gp5 complex has been thoroughly studied by many laboratories. gp5 is a 9.7 kDa protein and is mainly present as a dimer. The globular protein consists of numerous β sheets that fold into anti-parallel loops and expose positively charged residues. These residues are involved in the binding two strands of ssDNA building a 3-dimensional helical structure which has been modeled. In this model, two strands of the circular ssDNA are packed into a left-handed helix that is surrounded by gp5 dimers. The binding of gp5 to ssDNA occurs cooperatively to the phosphate backbone, but a phenylalanine and tyrosine residues are involved in contacting bases of the bound ssDNA.

Biosynthesis of M13 (fd, f1)

The Coat Proteins

Transcription of the filamentous DNA occurs early after the replicative RF I form has been generated. Early studies have shown that M13 is transcribed from the non-viral strand in 8 RNA species ranging from 8S to 20S. They are mostly generated from individual promoters that are recognized by the *E. coli* RNA polymerase holoenzyme. A strong rho-independent termination site is located shortly after the end of *gene 8* forming a tight hairpin loop structure and a rho-dependent termination site proximal to *gene 1*.

Translation of the 11 viral genes occurs shortly after infection by the host ribosomes. The ribosome binding sites (RBS) are located in a short distance before the start codon of *genes 1* to *9*, where the RBS for gp7 is located within *gene 5*, the RBS for gp6 is within *gene 3* and the RBS for gp1 is within *gene 6*. For gp9 the start codon overlaps with the stop codon of gp7. Interestingly, the coding sequences for gp1 and gp4 overlap with 7 codons and differ by their reading frame. *Gene 10* is located within *gene 2* in the same reading frame and also *gene 11* starts within *gene 1* in the same frame. Therefore, gp10 includes the same amino acid sequence as gp2 from residue 166–276 and gp11 is identical with gp1 from residue 241–348. This shows that the coding sequences of M13 are tightly packed and only the 503 bp intergenic region lacks any protein-coding information.

The Major Coat Protein gp8

Essential for the assembly of the filamentous phage is the expression of the 5 coat proteins gp3, 6, 7, 8, 9. They all are inserted into the membrane where the assembly of the phage particles occurs. gp8 is the major coat protein with more than 2500 copies per particle. It is first synthesized with a signal sequence of 23 amino acids that is cleaved off after membrane insertion. Leader peptidase (LepB) recognizes the transmembrane procoat proteins at the residues -1, -3 and -6 in the signal sequence following the “*von Heijne rules*”. The membrane insertion of procoat requires an essential membrane protein of the host, the membrane insertase YidC. YidC binds to the hydrophobic sequences of procoat with its hydrophobic slide structure leading to the integration of the procoat protein across the membrane. After cleavage by leader peptidase, the 50 amino acid long M13 coat protein exposes the N-terminal first 20 residues into the periplasmic space and the C-terminal 10 residues into the cytoplasm.

The exact mechanism of membrane insertion has been studied with the major coat protein of Pf3 *in vivo* and *in vitro*. This protein lacks a signal sequence but also requires YidC for membrane insertion. The Pf3 coat protein has been purified and added to YidC containing proteoliposomes which inserted the coat protein efficiently. Atto-labeled mutants of Pf3 and YidC allowed the calculation of the speed the membrane insertion reaction takes by single molecule Förster resonance energy transfer (smFRET) and is in the range of 10 ms. Disulfide cross-linking showed that the coat protein enters YidC step-by-step up the hydrophobic slide of YidC and the membrane potential dependent translocation step then moves the N-terminal domain of Pf3 coat from the hydrophilic groove inside YidC into the periplasm.

In the membrane, the M13 coat proteins oligomerize as shown by disulfide cross-linking. Possibly, these oligomeric forms interact with the gp1/11 packaging machine and cover the single stranded DNA. The four positively charged amino acid residues in the C-terminal tail of the coat protein might electrostatically interact with the negatively charged phospholipids of the DNA. When the number of the lysines was reduced the length of the phage particles increased correlating with the altered charge density. On the phage particle, gp8 interacts with neighboring gp8 by hydrophobic interaction in a tilted staggered arrangement (see section on the phage particle structure). The N-terminal region of the coat protein is negatively charged but is quite flexible for alterations. Antigenic peptides and display peptides have been incorporated into this region and were exposed on the phage.

The Minor Coat Proteins gp7 and gp9

The assembly reaction is initiated with the capping proteins gp7 and gp9. Both proteins are synthesized without a signal sequence but fractionate with the inner membrane. gp7 is a small 33 amino acid long single-spanning membrane protein. Its N-terminal region of 8 residues includes 3 negatively charged residues, whereas the C-terminal residue is an arginine residue. For the display of foreign peptides the PelB signal sequence was added to support the membrane insertion of gp7. Even in the absence of an added signal sequence gp7 was useful for phage display.

Gp9 has only 32 residues and is the smallest coat protein. The C-terminal region of 15 residues is positively charged and in the cytoplasm. It is unclear whether the N-terminus is exposed in the periplasm since there is no hydrophilic residue present. When the N-terminus was extended by 20 polar residues encompassing a T7 tag the protein was fully functional and complemented an M13am9 infection. The membrane insertion of this extended gp9 was dependent on the membrane insertase YidC and after insertion the N-terminal extension was digestible by proteinase K. It is possible that the non-extended gp9 protein inserts also spontaneously as was shown with artificial membranes. Therefore, gp9 can be used for phage display and if it is applied with a second display site at the base end of the phage particles (e.g., gp3) bi-functional phage can be designed.

Gp7 and gp9 presumably interact with the hairpin packaging signal to initiate DNA packaging at the membrane surface. Mutants which had the packaging signal deleted were compensated by plaque-forming phage mutations within genes 7, 9 and 1. gp7 can be co-immunoprecipitated with gp8 which suggests that once the formation of packaging complex is initiated the major coat protein is fed into the packaging machinery for assembly.

The Minor Coat Proteins gp3 and gp6

As the packaging process is approaching the end of the single stranded DNA circle, gp3 and 6 bind and terminate the phage assembly. gp3 is first synthesized with a signal sequence of 18 amino acid residues and inserted by the Sec translocase involving SecA. After cleavage it is a single-spanning membrane protein and has a large N-terminal domain of 378 amino acids in the periplasm and a cytoplasmic region of 5 residues. The membrane anchoring of gp3 has been studied in detail. When the length of the membrane anchor was reduced from 23 residues to 17 the topology was unchanged. Larger deletions, however, resulted in a periplasmic location. The periplasmic region of gp3 contains two β structured domains, termed D1 and D2. The two domains (later named as N1 and N2) are connected by a flexible hinge region that is functional during the phage infection process. Whereas N1 (residues 1–68) folds and unfolds rapidly N2 (residues 124–217) folding is slow followed by the folding of the hinge region and the docking of the two domains tightly together. This tight folding ensures that the phage particle is stable in changing environments. Following the two N-domains the periplasmic portion of gp3 contains a C1 and a C2 domain. Whereas C1 is important for phage stability, C2 is involved in the release of the secreted nascent phage progeny.

Gp3 has been extensively used for phage display technology. The random sequences encoding the display peptides are introduced between the signal peptide and the mature sequence of gp3. Therefore, the peptides are displayed on the phage at the very N-terminus not affecting the two β structured domains N1 and N2.

At the base of the phage filament gp3 is connected to gp6, a small very hydrophobic protein of 112 amino acid residues. From its sequence it is predicted to span the membrane three times with the C-terminus in the cytoplasm. In the phage, gp6 is required for the termination of the assembly reaction. Amber mutations cause the generation of polyphage. Based on this observation and the stability of the polyphage it has been concluded that gp6 first binds to the end of the nascent phage and gp3 then follows. Also gp6 has been used for phage display with extensions at its C-terminus.

Assembly and Secretion

The assembly of filamentous phage is initiated at the “morphogenetic signal” on the replicated M13 single stranded DNA (bases 5550–5577) which is a double-stranded hairpin structure close to the 5' end of the replicated ssDNA. The tip of the hairpin a GCA-loop might be the actual structure of the DNA that interacts with the membrane inserted gp7/gp9 initiating the assembly reaction. In the assembled phage, gp7 and gp9 that are located at the tip of the particle and are present with about 5 copies each, together forming the phage cap structure.

The membrane based assembly process is controlled by gp1 and its shorter version gp11 which starts at an internal gp1 codon for the methionine residue 241. The two proteins form a common oligomeric “preinitiation complex” in the membrane together with gp4 that is localized in the outer membrane. gp1 has a large N-terminal domain in the cytoplasm that contains an ATPase binding site with the typical Walker box elements. Mutations within these elements inhibit phage propagation suggesting that ATP hydrolysis is required for phage extrusion. Close to the membrane spanning regions of gp1 and gp11 are a characteristic pattern of positively charged residues similar to the pattern found in gp8. These are presumably involved in the transient binding of the extruding phage DNA molecule. The morphogenetic signal of the phage DNA contacts the gp1/11 complex in the inner membrane together with thioredoxin reductase TrxA of the host converting the preinitiation complex to an “initiation complex”. Since the enzymatic activity of TrxA is not required for phage propagation the contribution of TrxA is likely only structural, similar as it is for phage T7 replication.

The single stranded DNA that interacts with the gp1/11 complex is covered with multiple copies of gp5. The gp5 proteins are continuously displaced from the DNA as it enters the assembly machinery and within the machinery gp5 is replaced by the major coat protein gp8. gp8 exists as oligomers in the membrane and presumably, these are fed into the membrane spanning assembly machine laterally for assembly (Fig. 1). Since in the M13 phage particle the coat proteins are arranged as pentamers in so called five-start helices it is possible that the gp1/11 machinery has five lateral entrances for the gp8 proteins that all five simultaneously bind to the DNA. A model of a cooperative pentameric assembly of gp8 generating the phage has been proposed early on. According to this model, each of the added coat proteins would be followed by the next coat protein in a certain distance leading to the staggered and interdigitated subunit packing of gp8. In the phage, this results in a shingle-like arrangement of the coat proteins covering the particle. Thereby, the nascent filamentous phage particle is drilling itself out of the host cell (Fig. 1).

During the assembly process the growing nascent phage filament passes through the outer membrane with support of gp4. gp4 is a protein of 406 amino acid residues and is synthesized as a precursor of 426 residues. In the outer membrane gp4 is assembled into a 14-meric secretin structure with a central cavity of 6–8 nm forming a gated pore. This diameter allows the passage of the emerging phage particles that have a diameter of about 6 nm. The channel gating of the gp4 secretin is of functional importance since mutants in the respective regions of gp4 lead to a leaky phenotype of the host cells that also leads to an enhanced sensitivity towards antibiotics. In addition, the N-terminal portion of gp4 that is located in the periplasm makes contact to the gp1/11 assembly machine located in the inner membrane possibly forming a continuous structure. In accordance with this, a mutant in gp1 was found to be partially compensated by a mutation in gp4. However, the interaction between gp4 and gp1/11 might be weak since the two proteins are not co-purifying when extracted from cells.

Fig. 1 Model of M13 packaging. The membrane-inserted major coat proteins oligomerize and bind to the ssDNA in a shingle-like fashion catalyzed by the packaging motor gp1/11 and ATP.

Fig. 2 Infected cells extruding M13 phage particles visualized by the AFM. Samples were taken at 0, 5, 10 and 16 min post infection and recorded with the atomic force microscope. The bar is 1 μm . Courtesy of Martin Ploss.

The extrusion of the filamentous phage was visualized by atomic force microscopy (AFM). Synchronized by the infecting phage, the generation and extrusion of progeny phage from the host cells was observed already after 5 min and could be followed time-dependently reaching a maximum of extruding particles all over the cell surface after 16 min (Fig. 2). Judging from the length of the extruding particles the assembly and secretion is a fast process.

The phage assembly process is terminated by the two proteins gp6 and gp3. Presumably, they both enter the gp1/11 assembly machine when the extruding DNA molecule is entirely covered by gp8. As mentioned above, gp6 is most likely first assembled to the nascent phage followed by the binding of gp3 with its C-terminal region. It has been shown that gp3 and gp6 co-purified when extracted from phage. Mutations in gp3 and gp6 can lead to multiple length particles, also called polyphage. This clearly shows that the two minor coat proteins are involved in the termination step of the assembly. Normally, the size of the phage DNA determines the length of the filamentous phage.

Biotechnological Applications of Filamentous Phage

One of the first applications of M13 phage was its use as a DNA sequencing vector. Since the sequencing reaction *in vitro* is very efficient with single stranded DNA, foreign genes were cloned into M13. The ssDNA was extracted from the phage particles and sequenced with the “universal” oligonucleotide using radiolabeled nucleotides. The universal primer anneals shortly before the multiple cloning sites where the foreign genes were ligated.

Many applications are based on the phage display technology. The coat proteins (namely gp3, 6, 7, 8, 9) can be modified with protein domains that are exposed on the phage surface. These exposed domains can be used as binding components to a plethora of different targets and surfaces. The use of randomized oligonucleotides allows the generation of “display libraries” from which the optimal binders can be selected. Details are described in the recommended “further readings” section.

Due to their unique morphology with a length to diameter ratio of ≈ 130 , filamentous phages can be employed as scaffolds for nanotechnological applications. Many fascinating examples exist where the long and thin structure of the bacterial virus has been made use of to create wire-like structures for various applications. Many groups, especially the research group of MIT scientist Angela Belcher has shown the vast potential of creating virus-based hybrid materials. One such hybrid material consists of a genetically engineered multifunctional M13 phage that binds to carbon nanotubes via the coat protein gp8, which allowed to deposit amorphous FePO_4 in order to achieve high-efficiency electric conductivity. The phage-hybrid material resulted in the reduction of the electron transport from the highly resistive cathode to the conductive elements of the battery. The material displayed a superior performance to any previously engineered amorphous FePO_4 electrode, in terms of power performance and capacity. Filamentous bacteriophage can also be used as nucleation templates for the ambient temperature synthesis of nanowires with phase-changing properties (material capable of changing between two physical states). This is a particularly interesting

application as faster computers can be constructed by drastically reducing the time delays that occur in current architectures from the transfer and storage of information between silicon- and magnetic-based memories (usually milliseconds). Nanosecond time scale information storage can be achieved by specialized *segregating-binary-alloy-type phase-change-materials* (e.g., Ga-Sb-based systems), by employing a single memory structure. In purely inorganic materials, the disadvantages of such materials are the high energy consumption and high temperature-induced elemental segregation. This can be overcome by using filamentous phages as templates: By forming a filamentous phage germanium–tin oxide hybrid material, achieved via an electrostatic binding on the M13 virus coat proteins, wire-like *phase-change-materials* can be obtained. This wire-like structures displayed reliable and controllable phase-changing signatures, with tens of nanoseconds switching times and a great potential for building new and highly advanced computers. Filamentous phage particles have also been used to build a biological metal solar cell arrays that can convert the energy from light with high efficiency into electricity. The M13 phage was used to construct a 3D structure which proved to be highly efficient in light harvesting in specialized dye-sensitized solar cells (DSSCs). Again, the filamentous structure was used to deposit metals onto the phage coat proteins. In this case, gold nanoparticles were used, which in turn were encapsulated with titanium dioxide. This resulted in a plasmon-enhanced nano-wire photoanode. Another fascinating example is the use of M13 to prepare low density 3D aerogels, which are ultralight porous structures with excellent elastic behavior, allowing up to 90% material compression. By using peptide fusions on capsid proteins, inorganic materials can be attached creating inorganic aerogels. Such materials offer a plethora of possible applications, e.g., as bio-scaffolds, for the storage of hydrogen or energy, thermoelectrics, and catalysis. Not using filamentous phages as a wire or wire-network, a novel strategy for biocatalysis for the production of semisynthetic enzymes was developed by the incorporation of an enzymic motif into thermostable M13 phage coat proteins. Examples are phage particles that contain a site modeled after the active site of the enzyme carbonic anhydrase. Filamentous phages can also be employed as nanoparticles for imaging: For near-IR fluorescence imaging of tumors in deep tissues, genetically engineered multifunctional M13 phages were assembled with fluorescent single-walled carbon nanotubes as targeted probes for the specific uptake in prostate tumors.

Glossary

θ replication Circle-to-circle or θ -type DNA synthesis. It occurs when the replisome is assembled on a circular chromosome at the *ori* region, leading to its uni- or bidirectional replication. Its product is two catenated DNA molecules.

σ replication It is also referred as rolling circle replication. Its product is a concatemer generated by recombination-dependent DNA replication (RDR).

Concatemer A head-to-tail linear DNA molecule generated either by a replicative or by a recombination mechanism.

cos A DNA sequence recognized by the viral terminase to initiate and terminate encapsidation of a unit-length genome.

DNA synthesis To synthesize both DNA strands in a concerted and semiconservative fashion in the 5'→3' direction. One strand is synthesized mainly continuously (the leading strand) and the other is synthesized discontinuously (the lagging strand).

Headful packaging Processive viral DNA packaging along a phage DNA concatemer whose first cycle is initiated by an endonucleolytic cleavage at *pac*, and terminated by a sequence-independent cut that occurs when a threshold amount of packaged DNA is reached inside the phage capsid. The subsequent encapsidation cycle begins at the DNA end created by the headful cut, and processive headful

encapsidation cycles ensue. The DNA molecules encapsidated are terminally redundant (usually 1.02–1.1 longer than the genome size) and the order of genes is partially circularly permuted to an extent that depends on the concatemer size.

pac A DNA structure and sequence recognized by the viral terminase to initiate encapsidation by the headful packaging mechanism.

Preprimosome A protein complex that loads the replicative DNA helicase into DNA, and it is subsequently disassembled.

Primosome A protein complex composed of the replicative DNA helicase and the DNA primase, or a single helicase-primase protein. In some cases, a hybrid RNA-DNA primer is synthesized in concert with a DNA polymerase (DnaE) to initiate DNA synthesis.

Replication origin (*ori*) A locus at which a replication initiation protein binds or an RNA polymerase transcript melts the duplex at an adjacent AT rich region (DUE, for DNA-unwinding element). The resulting ssDNA regions act as loading site of the replicative helicase.

Replisome A protein machinery devoted to replicate DNA. In *Bacilli* it is composed of two replicative DNA polymerase holoenzymes (PolC and DnaE), the clamp loader DnaX-HolA-HolB (also termed $\tau\delta\delta'$), the processivity factor DnaN (also termed β clamp), and the primosome.

Introduction

Bacteriophages (or phages) provide the largest unexplored genetic reservoir and are the most common biological entities on earth. The large majority of phages with double-stranded (ds) DNA belong to the ancient *Caudovirales* Order (~97%), and their division is probably older than the separation of the three domains of life (Bacteria, Archaea and Eukarya). The *Caudovirales* Order is composed of three major Families: *Myoviridae* (~20% of total species of the Order), *Siphoviridae* (~68%), and *Podoviridae* (~11%) (Ackermann, 2003).

Bacteria of the Firmicutes phylum (Gram-positive cells with low dC + dG content in their DNA), which are placed at the earliest division of Bacteria, are predominant in a healthy gut microbiota. Among Firmicutes, the Class *Bacilli* includes bacteria with round- (termed coccus) or rod-like form (bacillus) that represent a major health burden in the community as well as in hospitalized patients as e.g., *Streptococcus spp.*, *Enterococcus spp.*, *Staphylococcus spp.*, *Listeria spp.* and several Genera from the *Bacillaceae* family. Thus, the inherent ability of phages to infect those bacteria and control their biomass turnover makes them ideal candidates to develop antimicrobial agents for pathogen-specific remediation (e.g., phage therapy). On the other hand, *Bacilli* phages infecting *Lactococcus spp.*, *Lactobacillus spp.*, *Leuconostoc spp.*, *Oenococcus spp.* as well as certain *Bacillaceae* are a major concern to dairy, wine, and meat bioprocesses. Understanding how these phages multiply is an essential step to harness the full potential of phage-based technologies and to generate novel strategies to combat industrial phage contaminations. Here, we describe present knowledge on the different strategies that *Bacilli* phages use to replicate their DNA. A representative phage from each of the major families of the Order *Caudovirales* that infects the model bacterium *Bacillus subtilis* was chosen (Table 1), and compared with other *Bacilli* phages.

Table 1 Phage- and Host-encoded proteins involved in DNA replication

Function	SPO1	T4 ^a	SPP1	ϕ 29	Host
ssDNA binding	?	gp32	gp36	gp5	SsbA
Replisome organizer	–	–	gp38	–	DnaA/PriA
Protein priming	NA	NA	NA	gp3/TP	NA
Replication mediator (RMP)	?	gp59	gp38-gp39	gp6	PriA-DnaB-D-I
Replicative helicase	gp21.1	gp41	gp40	–	DnaC
Helicase loader	–	–	gp39	–	DnaB-D-I
DNA primase	gp21.95	gp61	host	–	DnaG-DnaE
DNA polymerase ^b	gp31 (A)	gp43 (B)	host	gp2 (B)	PolC, DnaE (C)
Clamp loader	?	gp44/62	host	–	DnaX-HolAB
Sliding clamp	?	gp45	host	–	DnaN
Topoisomerase	J1 mutation	gp39/52/60	host	–	GyrAB, ParCE

DNA helicase	–	Dda	?	–	RecD2
HJ resolvase	gp24.1	gp49	gp44	–	RecU

^aEarly and late replication of large dsDNA viruses of the Myoviridae family was reconstituted *in vitro* only for phage T4 that infects *Escherichia coli*. Therefore, T4 is depicted for its comparison with SPO1.

^bThe family to which the replicative DNA polymerase belongs is denoted within parentheses.

Note: NA, not applied; ?, unknown.

The majority of cells and their viruses initiate DNA replication by building an *orisome*. In the host cell an ATP-dependent replisome organizer protein(s) binds to multiple sites at the *ori* region. This interaction leads to a conformational change that exerts a mechanical force for strand opening of an adjacent AT-rich region termed DUE (for DNA-unwinding element) and recruits, directly or indirectly, the replicative helicase to establish bidirectional replication forks. Most viruses of the Order *Caudovirales* use their own replication machinery or a combined action of viral and host functions, while a minor number of them encodes only for one function (the *ori* region) that is essential for initiation of DNA replication, and relies on the host machinery for replication elongation, as lactococcal phage c2 (and perhaps sk1) of the *Siphoviridae* Family.

The dsDNA phages have evolved an efficient and economical process for amplification of over 100 virus genome copies within minutes. They use three different mechanisms to initiate DNA synthesis. The majority of those phages use two different replication modes (early and late) to replicate their linear or circular genomes to generate the concatemeric DNA substrate for genome packaging into preformed viral procapsids (or proheads). A less common approach is the replication of linear unit-length genomes by a protein priming mechanism (Salas, 1991). These different strategies to initiate DNA replication and the replication mode used are not restricted to a specific tailed phages Family. For example, within the *Podoviridae* Family, phage T7 uses RNA polymerase to initiate DNA replication as earlier described for plasmid ColE1 (Masukata *et al.*, 1987), phage P22 uses an ATP-independent replisome organizer protein to start DNA synthesis, whereas phage ϕ 29 initiates DNA synthesis by a protein priming mechanism.

Viruses, in general, and the different Families of dsDNA phages that infect bacteria of the *Bacilli* class in particular, do not have a universal set of genes. They have a core of ancient virus hallmark genes shared within viral families, combined with non-conserved genes that build genomes with a mosaic organization. Viral infection and horizontal gene transfer strongly contribute to spread and swap genetic information among viruses leading to this mosaicism that obscures their phylogenetic relationship. Such effect is also observed in the genome module encoding the DNA replication and recombination functions of *Caudovirales*. In this article we summarize current knowledge on the replication strategies of the large genome size SPO1-like viruses of *Myoviridae* (with a contractile tail); the middle-size SPP1-like viruses of *Siphoviridae* (with flexible, non-contractile tail); and the small-size ϕ 29-like viruses (with a short, non-contractile tail) of *Podoviridae* Family.

With the exception of ϕ 29-like viruses, the replication of tailed phage genomes starts by an early replication mode that generates a template substrate for late replication. Late replication uses a recombination-dependent replication (RDR) mode to yield the head-to-tail concatemer that is cut at specific site(s) *cos* (to render unit-length genome) or *pac* (redundant ends) for packaging into viral procapsids. Therefore, recombination is an essential step in phage DNA metabolism. Phages can use a *pac* site and a headful packaging mechanism to generate mature terminally redundant DNA molecules with or without circular permutation (Casjens, 2011; Rao and Feiss, 2015). The *pac*-containing phages constitute major vehicles for horizontal gene transfer, including virulence and antibiotic resistance genes. Alternatively, tailed phages use *cos* sites in the replicated genome concatemer to initiate and terminate DNA encapsidation, which generates unit-length packaged DNA molecules (Casjens, 2011; Rao and Feiss, 2015). Other phages like SPO1 package DNA molecules that have a non-permuted, several kb-long, terminal redundancy at their ends. Since the substrate used for processive packaging is a concatemer, their terminal redundancy must be generated by *de novo* DNA synthesis in concert with DNA packaging (Stewart *et al.*, 2009). The underlying mechanism remains unknown.

Fig. 1 Genome overview of the replication module of SPO1-like phages. The arrows indicate the direction of gene transcription. Relatedness is derived from P-BLAST comparison of phage-encoded products. The color of each gene identifies its classification in functional groups: DNA recombination (red), DNA replication (blue), and related functions (black). The lengths of the interspersed regions are indicated. The names of the genes are labeled above the arrows and their putative function is annotated. Hel: helicase; RDH: replicative DNA helicase; SbcD and SbcC: nuclease; SbcCD; Prim: primase; Res: holliday junction resolvase; Pol: DNA polymerase; EXo: 5'→3' exonuclease; Lig: DNA ligase; PcrA: helicase; Rec: RecA-like recombinase. The genome sequences accession numbers are NC 011421, MF422185, NC 020873, AY682195 and KP881332.

Finally, ϕ 29-like viruses initiate DNA replication by protein priming that is extended by the DNA polymerase. The synthesized unit-length genome is subsequently packaged with a terminal protein (TP) covalently linked at the 5'-end into an empty prohead (Salas, 1991).

Phages with homology to the SPO1, SPP1 or ϕ 29 prototype genomes can show three degrees of evolutionary relatedness: (i) those whose complete genome has strong nucleotide sequence identity to the phage prototype; (ii) those with a mosaic genome organization, having discrete modules with significant degree of nucleotide sequence homology to the phage prototype; and (iii) those whose sequence identity between the different replication proteins is low, but their coding genes order is conserved. Therefore, our analysis of the replication machinery of SPO1-, SPP1-, and ϕ 29-like phages will not be restricted to those with close phylogenetic relatedness. We will use a *sensu lato* classification to include viruses with conserved synteny of DNA replication gene modules with respect to the prototype virus for the analysis of their replication machineries.

DNA Replication of SPO1-Like Viruses

The genus SPO1-like virus, including the prototype phage SPO1 that infects *B. subtilis*, is in the process of being renamed genus Okubovirus in honor of Shunko Okubo, who isolated SPO1 and carried out the first genetic studies of this myovirus. It includes large dsDNA viruses with a genome size > 100 kb. *B. subtilis* spp SP82, 2C, SP8, ϕ 25, H1, ϕ e and SP5C phages show a significant degree of nucleotide sequence identity to phage SPO1 (group i). A comparative analysis of available phage genome sequences identified two other groups of phages based on their level of relatedness to SPO1: *Bacillus* phages SP10 and Bc431v3, *Listeria* spp P100 and A511; *Staphylococcus* spp phages K, G1, P1, S3K, ϕ 812, Twort, Stau2; and *Lactobacillus* spp phage LP65 and Lb338-1; *Enterococcus* spp phage ϕ EF24C. Phages SPO1 (representative of group i), SP10 and Bc431v3 (group ii) and LP65 and Stau2 (group iii) are depicted in Fig. 1. Replication and recombination genes are clustered in a region of their core genome. They are spaced either by genes encoding for a function optimizing viral DNA amplification or for proteins of unrelated/unknown function.

The genome of SPO1-like viruses is large (130–160 kb-long) and thymine is replaced by 5'-hydroxymethyluracil (hmU). DNA replication starts from at least two replication origins. Although SPO1 is the best-characterized member of this group, there is limited information on its DNA replication mechanism. Here, SPO1 protein candidates participating in the process will be discussed, and potential mechanistic similarities with the well-studied DNA replication of myovirus T4 will be addressed.

At early times of infection, SPO1 DNA replication initiates at specific origin sequences by RNA polymerase transcription to generate a stable untranslated transcript. This RNA remains attached to its template to form a strand displacement RNA (R-loop). This structure maintains the DNA strands melted at the DUE region in a process that is independent of recombination proteins, and DNA replication starts. As infection progresses, a RDR mechanism becomes predominant and the origin-dependent replication mode is turned off. The SPO1-encoded DNA primase (Prim, gene product (gp) 21.95), replicative DNA helicase (RDH, gp21.1), DNA polymerase (Pol, gp31) and 5'→3' exonuclease (Exo, gp32.85) (Fig. 1) may have their functional counterparts in the host DnaG, DnaC, DNA PolII and YcpP proteins, respectively, but these host functions are unable to substitute for the SPO1-encoded proteins (Table 1). When the RDR mechanism is turned on, phage SPO1 probably relies on phage- and host-encoded recombination machineries. Although phage T4 codes proteins with single-stranded DNA-binding and recombinase activities essential for its replication, none of the SPO1-encoded products shows significant similarity to proteins with related functions (Table 1). However, other phages of this Family encode an ATP-dependent recombinase (Rec, counterpart of host RecA)

downstream of the viral-encoded DNA polymerase (Fig. 1), suggesting that in these phages initiation of late replication is controlled by a viral protein. At present, it is unknown if host RecA is able to substitute for the viral encoded counterpart.

Some of the SPO1 DNA replication functions for which no viral gene was identified could be performed by uncharacterized phage proteins. For example, no gene product shows significant sequence similarity to host DNA gyrase. However, SPO1 infection requires a DNA topoisomerase function and SPO1 mutants can replicate in the presence of DNA gyrase inhibitors, suggesting the presence of a viral topoisomerase (Table 1). In late replication, the host-encoded recombination machinery might initiate RDR. Then, SPO1-encoded DNA helicases Hel and PcrA-like (gp19.5 and gp34.33) could prevent over-replication at displacement loops (D-loops) formed by homologous recombination or are involved in the replication of branched intermediates. Branched replication intermediates could be resolved by the phage putative HJ-specific resolvase Res (gp24.1) (Table 1), although some viruses might have lost it, and rely on a host function (Fig. 1). The SPO1 gp21.1 and gp21.9 proteins share homology with the host SbcCD complex, which cleaves DNA ends, hairpins, abnormal replication intermediates, and terminal DNA structures preparing DNA ends for RDR, in a way similar to the eukaryotic Rad50-Mre11 complex. Finally, the gp32.95 LigD-like DNA ligase could seal hmUra containing DNA ends. The majority of SPO1 genes are co-oriented with the DNA replication RDR direction. One strategy to avoid deleterious head-on replication-transcription conflicts is to use the helicase gp34.33 together with the gp21.1-gp21.9 complex to promote replisome progression and to reduce head-on conflicts.

The detailed mechanism of DNA replication of SPO1-like viruses (*Spounavirinae* subfamily) is unknown. Their genome core is reminiscent of the one from *E. coli* T4-like phages (*Tevenvirinae* subfamily). Since T4 DNA replication was extensively studied and reconstituted *in vitro* (Nossal, 1983; Mosig, 1998; Kreuzer, 2000; Benkovic and Spiering, 2017; Barry *et al.*, 2018), we revisit its molecular mechanism as a model for the large viruses of the *Myoviridae* Family. In phage T4, cytosine is replaced by hydroxymethylcytosine (hmC). All the proteins necessary for replication of its linear and/or circular genome are encoded by the phage, with the exception of the RNA polymerase that is provided by the host cell.

Early after infection, T4 DNA replication starts from the *oriE* locus close to an early promoter (major origin) and from four secondary origins (*oriA*, *oriC*, *oriF* and *oriG*) located near middle promoters. The primary and secondary origins are located just upstream of a DUE. RNA polymerase synthesizes a RNA that binds stably to its template, forming an R-loop. Following processing by T4-encoded RNaseH, this untranslated transcript serves as a primer to initiate DNA synthesis. In the R-loop the nascent RNA anneals to the coding DNA strand, leaving the displaced noncoding DNA coated by the single-stranded DNA binding protein (Ssb) gp32. The acidic C-terminal tail of gp32 interacts with the replication mediator protein (RMP) gp59, the family B DNA polymerase gp43, the recombinase UvsX, recombination-mediator protein UvsY, the DNA helicase Dda, and the primase gp61 (Table 1). The interaction of gp32 bound to ssDNA with gp59 and the replicative gp41 helicase loads both proteins onto the viral linear and/or circular genome (Table 1). Gp59 binds to the R-loop-dependent replication origin. Gp41 then interacts with the gp61 whose recruitment promotes assembly of the T4 primosome. The primosome loads the T4 DNA polymerase holoenzyme, composed of gp43, the sliding clamp gp45, and the clamp loader gp44/gp62.

Leading strand synthesis is initiated at the 3'-OH end of the RNA primer by the gp43-gp4-gp44/gp62 complex. After the gp59 mediator frees gp41, the primosome allows gp41 unwinding of the substrate in the 5'→3' direction, gp61-mediated synthesis of the lagging strand primer, and gp32 binding to the ssDNA regions (Table 1) (Benkovic and Spiering, 2017; Barry *et al.*, 2018). Gp43 synthesizing the lagging strand remains in contact with the leading strand polymerase at the replication fork. This organization folds the lagging strand into a 700–1500-nucleotide loop coupling leading and lagging strand synthesis, according to the *trombone model* of replication. The encounter of the replisome with the 5'-end of the previous synthesized Okazaki fragment triggers dissociation of the lagging-strand replisome that disengages from gp45, leaving the clamp protein bound to the lagging-strand. Synthesis of a new Okazaki fragment ensues (Barry *et al.*, 2018).

In the large Myoviruses of the T4 and SPO1 groups, early DNA replication starts from an internal origin of replication in a linear molecule. This implies that when viral replication reaches the chromosome ends, the synthesized DNA molecules are shorter than unit length. The leading strand is replicated to the 5'-end yielding a 3'-tailed duplex while lagging strand replication leaves a ssDNA region at both ends resulting in a 5'- and 3'-tailed duplex replicated DNA molecule. The 3'-ssDNA ends coated by gp32 are competent for recombination by strand invasion. At late stages of phage T4 infection, the UvsW DNA helicase inactivates initiation from R-loops by unwinding potential primer transcripts that may have persisted or were synthesized during late infection, ensuring that RDR predominates. The ATP-dependent UvsX recombinase, loaded by the UvsY recombinase mediator, polymerizes on the 3'-tailed substrate generated by early replication. UvsX-mediated DNA pairing forms a displacement loop (D-loop) at a homologous region on the linear DNA template to initiate DNA synthesis by RDR (Table 1) (Kreuzer, 2000). Viral-mediated RDR resembles eukaryotic break-induced replication, but the latter is mutagenic and prone to chromosome rearrangements (Llorente *et al.*, 2008). Unidirectional replication, initiated from this invading 3'-end that is the primer for leading strand replication was proposed to duplicate most of the T4 DNA molecule. Multiple strand invasion events generate a complex branched network as the infection progresses. This replication mode promotes the appearance of replicating DNA intermediates containing multiple covalently linked copies of the genome. The Holliday junction (HJ) resolvase gp49 (also termed Endo VII) cleaves the network of chromosomes and such debranching generates linear concatemeric DNA molecules (Mosig, 1998). The viral terminase initiates packaging at *pac* within these concatemers into empty T4 phage proheads by a processive headful mechanism. DNA molecules slightly longer than the unit-length of a T4 genome are encapsidated, resulting in a population of terminally redundant and circularly permuted packaged T4 chromosomes. This differs from SPO1 that uses a substrate concatemer to package, by an unknown mechanism, DNA molecules that have a several kb-long terminal redundancy (Stewart *et al.*, 2009).

Fig. 2 Genome overview of the replication module of SPP1-like phages. The figure organization and symbology are as in Fig. 1. The protein functional annotation is: Exo: 5'→3' exonuclease; Rec: Recombinase; Ssb: single-stranded DNA binding protein; Rep: replisome organizer; RMP: replisome mediator protein; RDH: replicative DNA helicase; Res: Holliday junction resolvase. oriL and ori are origins of replication. The genome sequences accession numbers are X97918, KJ159566, DQ517338 and KC342645.

Another mechanism proposed to generate the phage T4 DNA concatemer is that 3'-ssDNA ends of the terminal redundant region pair, leading to a circular genome that becomes supercoiled by the action of the T4 DNA topoisomerase (the gp39-gp52-gp60 complex). Then, most of T4 DNA replication forks are initiated by UvsX DNA pairing and D-loop formation at a homologous region on a supercoiled circular DNA template. The gp59 mediator loads the T4 primosome onto the displaced ssDNA coated by gp32. The primosome, in concert with gp32, recruits the T4 DNA polymerase holoenzyme. In the presence of the T4 DNA topoisomerase, the DNA polymerase holoenzyme catalyzes DNA synthesis that begins at the 3'-OH end of the invading strand. DNA is synthesized continuously on one template strand, as in the leading strand of a replication fork, and discontinuously on the other template strand (Okazaki fragments) by a semiconservative mechanism. In one of the models, the circular DNA is then nicked to generate linear dsDNA concatemers by σ replication (Barry *et al.*, 2018) that are the substrate for DNA packaging. If the replication machinery stalls by an unrepaired DNA lesion, the phage RDR system rescues the stalled or collapsed fork. The UvsW DNA helicase can catalyze the regression of a stalled replication fork into a HJ-like structure that was postulated to be an intermediate in an error-free DNA damage tolerance pathway. The T4 gp46/gp47 exo/endonuclease and the Dda DNA helicase play a critical, although still poorly defined, role in replication restart. Finally, the gp30 DNA ligase could seal hmC containing DNA ends.

DNA Replication of SPP1-Like Viruses

B. subtilis phage SPP1 is the best-characterized member of middle-sized viruses from the *Siphoviridae* Family that infects bacteria of the *Bacilli* Class. Currently, phage SPP1 is included in the unassigned viruses of the Family, in spite of the fact that its DNA replication and packaging machineries as well as the viral particle assembly mechanisms are among the best characterized within the *Siphoviridae*. This calls for definition of a SPP1-like genus. A comparative analysis of the complete SPP1 genome shows that *B. subtilis* phages SF6, 41c, ρ 15, Lurz2 and Lurz3 have strong nucleotide sequence identity to phage SPP1, defining group (i). The *Bacillus spp* phage PM1 has discrete modules with significant nucleotide sequence identity to phage SPP1. Phage GBK2 has no homology at the DNA sequence level but has extensive similarity at the protein level, particularly in case of the DNA replication proteins whose coding genes order is co-linear with the SPP1 genome (Fig. 2). Finally, the *Staphylococcus spp* phages 80 α , ϕ 11 and JS01; *Lactobacillus spp* phage LL-H; and *Streptococcus spp* phage Sfi11 viruses show a conserved gene order of the DNA replication module with phage SPP1. Phages SPP1 (representative of group i), GBK2 (group ii) and 80 α and JS01 (group iii) are depicted in Fig. 2. All these phages package their DNA by a headful mechanism, generating encapsidated chromosomes with terminal redundancy and partial permutation.

Phages of this group replicate, most likely, their 40–50 kb genome using a mechanism similar to phage SPP1. At early times of infection, the SPP1 genome circularizes and replication is initiated at a specific and discrete replication origin sequence (*oriL*) in a process that resembles host chromosome replication. The early (θ -type) and late (σ -type) replication modes rely on early transcribed SPP1 genes. Early replication requires the essential SPP1-encoded replisome organizer (Rep, gp38), replication mediator protein (RMP, gp39) and replicative DNA helicase (RDH, gp40). As the infection progresses, σ -type concatemeric DNA replication becomes predominant and θ -type *ori*-dependent replication is turned off. The switch of replication mechanism relies on recombination proteins: the SPP1-encoded ATP-independent recombinase (Rec, gp35), a 5'-3' exonuclease (Exo, gp34.1), a single-stranded DNA binding protein (Ssb, gp36), and a Holliday junction resolvase (Res, gp44). In certain phages the initiator and mediator functions might be fused in a single polypeptide (Rep-RMP: phage 80 α gp20 and phage JS01 gp33) (Fig. 2) while the single-stranded DNA binding protein, the 5'-3' exonuclease and the HJ resolvase can be substituted by host encoded functions. The essential recombinase (Rec) can belong either to the Rad52 superfamily of recombinases (defining the Res β [SPP1 gp35, GBK2 gp39], Sak [80 α gp16] and Erf [C2 gp8] subfamilies of recombinases) or to the RecA-like superfamily as the ATP-dependent Sak4 recombinase (ϕ 11 gp12). The HJ resolvase (Res), like gp44 of SPP1, belongs to the RusA-like superfamily (Fig. 2).

SPP1 relies on numerous host proteins (the SPP1 *missing* functions) that are essential for its DNA replication, namely PolC, DnaE, DnaN (β -clamp), the DnaX-HolA-HolB or $\tau\delta\delta'$ complex and DNA gyrase. Cellular functions can also replace the non-essential gp34.1, gp36 and gp44 proteins. Although the lack of gp34.1 and gp36 is detrimental, the absence of gp44 has only a marginal effect on SPP1 multiplication. Initiation of circle-to-circle θ DNA replication and the late σ RDR (rolling circle replication) have been reconstituted *in vitro* (Seco and Ayora, 2017; Seco *et al.*, 2013).

After entry of the SPP1 linear chromosome in the *B. subtilis* cytosol, viral or host homologous recombination functions use the viral chromosome terminal redundancy to circularize the SPP1 genome, and the host DNA gyrase supercoils the circular DNA. The viral genome contains two replication origins (*oriL* and *oriR*) located ~ 13 kb apart in the circularized genome. The *oriL* sequence lays within the gene of the ATP-independent replisome organizer gp38 and *oriR* in an intergenic region transcribed late. Both *oriL* and *oriR* contain a different number of gp38-binding boxes (boxes A and B).

DNA replication is initiated by the preferential binding of gp38 to *oriL* that induces a localized unwinding of the adjacent AT-rich region on the supercoiled DNA template. The replication mediator gp39, which is an intrinsically disordered protein, interacts with the replicative helicase gp40 and with the replisome organizer gp38. Gp40 promotes gp39 protein folding to form a double hexamer structure together with gp40. The gp39-gp40 complex has neither ATPase nor helicase activity. Gp38 bound to *oriL* interacts with gp39 and loads the gp39-gp40 complex to the DUE region created when gp38 is bound to *oriL*. Gp39 loads and locks gp40 on the *oriL* lagging strand region until the gp38-gp39 complex is disassembled. Concomitantly with gp38-gp39 dissociation, gp36 binds to the ssDNA, and gp40 becomes free of the inhibition exerted by gp39. The hexameric replicative gp40 DNA helicase hub interacts with DnaX (or τ subunit) that is a component of the pentameric DnaX₃-HolA-HolB (also termed $\tau_3\delta\delta'$) complex, with the DnaG primase, and with the DnaE polymerase (Table 1). Then, the $\tau_3\delta\delta'$ complex loads both family C DNA polymerases (PolC and DnaE) and two sliding clamps (DnaN) to assemble the functional replisome (Seco and Ayora, 2017). Unidirectional leading and lagging strand synthesis is initiated at *oriL*. Priming of both strands is carried out by the DnaG-DnaE complex (like eukaryotic DNA polymerase α) that synthesizes a RNA-DNA hybrid. This hybrid is further extended by PolC in the context of the full replisome (i.e., in a complex with DnaN-DnaX-HolA-HolB) and catalyzes unidirectional replication of both strands (Table 1). DNA gyrase is required to remove positive supercoiling produced by the advance of the replication fork on the circular DNA template. The DnaG primase actively contributes to DNA polymerase switch at the leading strand, by inhibiting DnaE and stimulating PolC-mediated leading strand synthesis. On the other hand, gp36 and gp40 bound to the lagging strand recruit the DnaG-DnaE complex. This complex synthesizes the RNA-DNA hybrid while gp36 inhibits DnaE and stimulates PolC (Seco and Ayora, 2017). The replisome catalyzes discontinuous synthesis using the lagging strand template (Okazaki fragments) by a leading and lagging strand coupling via a semiconservative mechanism of DNA synthesis (trombone model). The encounter of the replisome with the 5'-end of previous synthesized Okazaki fragment triggers the dissociation of the lagging-strand replisome that disengages from the DnaN clamp leaving it bound to the lagging-strand.

After one or a few rounds of circle-to-circle DNA synthesis this θ mode of replication is turned off and SPP1 replication switches to linear concatemeric DNA replication (σ mode). The switch was proposed to be triggered by stalling replication fork progression (*road blocking*) by gp38 bound to *oriR*. Seven SPP1-encoded proteins are involved in the process of resuming replication at the stalled fork: four essential proteins (gp38 and gp39, working as a preprimosomal proteins, gp40 and gp35) and three partially dispensable proteins (gp34.1, gp36 and gp44). A branch migration translocase might regress the stalled fork leading to a Holliday junction (HJ) like structure. This extruded HJ can be cleaved by the gp44 HJ resolvase to generate a one-ended double strand break. The 5'→3' exonuclease activity of gp34.1 generates the 3'-tailed substrate required for gp35 activity (Table 1). Gp35, in concert with gp36, catalyzes DNA pairing and D-loop formation at a homologous region on an intact DNA template to initiate homology-directed RDR. Host RecA recombinase cannot replace for the gp35 activity. Gp39 in the preprimosome gp38-gp39 complex loads the replicative gp40 helicase that orchestrates assembly of the active replisome, as described above for the θ -type replication mode, initiating σ -type DNA replication. Two different mechanisms were proposed to achieve concatemeric DNA synthesis (Lo Piano *et al.*, 2011). The first is a bubble migration mechanism that invokes conservative DNA synthesis. The second invokes the action of the gp44 resolvase, or its cellular equivalent, to cleave and rejoin the D-loop structure such that a "rolling-circle"-like mechanism of DNA replication (σ -mode) occurs.

The σ replication mode generates a long linear concatemer. The SPP1-encoded terminase initiates DNA packaging by cleavage at the *pac* sequence that occurs only once along a substrate concatemer. The packaging cycle is terminated by a non-specific sequence cut determined by the amount of DNA inside the capsid, yielding packaged molecules longer than the phage genome (headful packaging mechanism) (Oliveira *et al.*, 2013). Processive headfuls are then sequentially packaged from the concatemer, generating a population of mature chromosomes with terminally redundant and partially circularly permuted sequence.

DNA Replication of ϕ 29-Like Viruses

B. subtilis ϕ 29 phage is the best-characterized member of small-sized viruses from the *Podoviridae* Family that infect bacteria of the *Bacilli* Class. Currently the Genus ϕ 29-like virus is in the transition to be renamed Salasvirus in honor of Margarita Salas, who has worked on ϕ 29 for over five decades. A comparative analysis of the complete genomes of *Bacillus* spp phages Nf, Goe1, ϕ 15 and PZA show strong nucleotide sequence identity to the ϕ 29 genome. All members of the ϕ 29-like genus seem to have a similar core genome and a conserved organization, with phage PZA exhibiting the particularity of an inversion of the left early genome region (Fig. 3). In the ϕ 29-like Genus there are phages with a mosaic genome organization, which have discrete modules with significant degree of

Fig. 3 Genome overview of the replication module of $\phi 29$ -like phages. The figure organization and symbology are as in Fig. 1. The small filled square denotes the TP bound to the 5'-end of the genome. The protein functional annotation is: Pol: DNA polymerase; TP: terminal protein; Ssb: single-stranded DNA binding protein; DBP: double-stranded DNA binding protein. The genome sequences accession numbers are NC 011048, PZACG, X99260, MF156577 and MH817022.

nucleotide sequence identity, as *Bacillus* spp phages GA-1, B103, Juan, BthP-Goe4, and Goe6; *Staphylococcus* spp phages P68 and ϕ IPLA7; and *Streptococcus* spp Cp-1, Cp-5, Cp-7, and Cp-9. Phages $\phi 29$ and PZA (representatives of group i), B103 (group ii) and Juan and BthP-Goe4 (group iii) are depicted in Fig. 3. The protein-priming DNA replication mode of $\phi 29$ -like viruses generates a linear unit-length molecule with a terminal protein (TP, also termed gp3 in $\phi 29$) at the 5'-end. The TP and a RNA molecule are essential for packaging of a unit-length viral genome into empty proheads.

All $\phi 29$ -like viruses have a linear dsDNA with a TP covalently linked to the DNA ends through a phosphoester bond between the OH group of a serine (e.g., $\phi 29$) or threonine (Cp-1) residue in the TP and the 5'-dAMP embedded within a DNA short inverted terminal repeat (ITR). The ITR length varies among phages of the $\phi 29$ Genus. The $\phi 29$ DNA replication system was reconstituted *in vitro* and will be described as the model for this group of phages (Salas, 1991; Salas *et al.*, 2016). In contrast to the complexity of other reconstituted replication systems, efficient synthesis of the $\phi 29$ genome can be accomplished *in vitro* with only four phage proteins. They are the double-stranded $\phi 29$ DNA-binding protein (DBP) gp6, the single-stranded DNA binding protein (Ssb) gp5, TP gp3, and the family B DNA polymerase (Pol) gp2. Gp2 couples DNA polymerization to strand displacement. This monomeric DNA polymerase also shows 3'→5' exonucleolytic activity, enabling proofreading. Its helix destabilizing activity, makes strand displacement by an accessory DNA helicase unnecessary.

Upon delivery of the $\phi 29$ DNA into the host cytoplasm, the parental TP covalently linked to each 5'-end of the genome associates with the bacterial nucleoid (Muñoz-Espin *et al.*, 2010). The abundant replication mediator gp6 binds along the $\phi 29$ DNA to form a nucleoprotein complex on viral DNA. This complex unwinds the ends of the DNA helix to facilitate loading of the heterodimer formed between a free TP and gp2 at a TP-DNA end. This TP-DNA end acts as the origin for replication. The DNA polymerase then catalyzes the formation of a phosphoester bond between a dAMP and the hydroxyl group of a Serine residue of the free TP, giving rise to the TP-dAMP initiation complex. The initiation reaction is directed by the second T at the 3'-end of the six nucleotides long ITR (3'-TTTCAT-5') present at the extremity of the $\phi 29$ DNA molecule. After, the TP-dAMP complex translocates one position backwards to recover the information corresponding to the first T on the template strand. The second T serves again as template for the incorporation of the following nucleotide (*sliding-back mechanism*), followed by addition of five nucleotides. Any mis-incorporated nucleotide in the TP-dNMPs covalent complex is not a substrate for the 3'→5' exonuclease proofreading activity of the $\phi 29$ DNA polymerase. Replication fidelity during the initiation reaction thus relies on the sliding-back mechanism in phages that initiate replication by protein priming. After initiation and sliding back, the $\phi 29$ DNA polymerase/primer TP heterodimer undergoes structural changes during incorporation of 6–9 nucleotides (transition stage). The DNA polymerase dissociates from the primer TP when nucleotide 10 is incorporated into the nascent DNA chain, shifting to the elongation mode.

The polymerase dissociated from the TP-gp2 heterodimer catalyzes highly processive DNA synthesis coupled to strand displacement of the non-template strand that is coated by gp5. The replication of both strands proceeds continuously from each terminal priming event (type I replicative intermediates). When the two replication forks moving in opposite directions meet, the type I replicative intermediate gives rise to two physically separated type II replicative intermediates. These molecules consist of full-length DNA in which a portion of the DNA, starting from one end, is dsDNA and the portion spanning to the other end is ssDNA. Once replication of both strands is accomplished, the two DNA polymerase molecules dissociate from the viral DNA to start initiation of replication in a new $\phi 29$ DNA molecule. The transcription machinery could be an obstacle to type I replicative intermediates and head-on and co-directional collisions could stall the replisome, leading to reassembly of the replication machinery. The small-size $\phi 29$ -like viruses do not encode for replication restart functions, suggesting that if replisome stalling occurs, the re-initiation relies on host functions.

Nomenclature

CTD C-terminal domain of a protein

EC Transcription elongation complex

gp Gene product

IC Transcription initiation complex

NTD N-terminal domain of a protein

Glossary

Lytic phage Phage that infect, takeover the host, make progeny, and lyse the cell.

Non-template strand The DNA sequence that will be the same as the RNA, 'the coding strand'.

Promoter DNA sequence that sets the start site for transcription initiation by RNA polymerase.

Template strand The DNA sequence that is copied by RNA polymerase during transcription. It will be the complement of the RNA sequence.

Introduction

Lytic phage, which infect, make progeny, and lyse the cell, need to rapidly takeover host resources in order to reprogram the host for phage development. Regulation of phage and host gene expression through transcriptional control is the primary mechanism for this appropriation of the host machinery. To accomplish this, phage-encoded proteins can inhibit host gene expression, redirect the host RNA polymerase to phage genes, and/or function as a new RNA polymerase. Here we discuss mechanisms used by the model bacteriophages T4, T7, and N4, as well as phages within those families.

Transcription Initiation and Elongation by Host RNA Polymerase

When a lytic phage enters the cell, it must first manage the host RNA polymerase (RNAP), by redirecting it to phage promoters and/or by inhibiting some or all of its host activity. Bacterial RNAPs belong to the family of multi-subunit polymerases that are highly conserved throughout biology. They consist of a multisubunit core that contains the RNA synthesizing activity and a specificity subunit, called σ factor, that recognizes the promoter sequence and selects the start site for transcription. In bacteria, the core is typically composed of 5 proteins: β , β' , two α 's, and ω . σ factors include a primary σ , such as σ^{70} in *E. coli*, which is used during exponential growth, and alternate σ 's, which are used under different growth conditions or times of stress. The σ^{70} family, the largest group of σ factors, shares regions of sequence and structural homology. For the primary σ 's, these are divided into Regions (R) 1, 2, 3, and 4, which can be further subdivided based on function (R1.1, R1.2, etc.).

Structures of multi-subunit RNAPs, together with decades of biochemistry and genetics, have revealed molecular details about how bacterial RNAPs initiate, elongate, and terminate transcription. We use the well-studied *E. coli* RNAP as the example here (Figs. 1 and 2(A)). The β and β' subunits of the core create a crab-claw like structure, with the active site for RNA synthesis at the center of the claw. The N-terminal domain (NTD) of one α ($\alpha 1^{NTD}$) interacts with β , while $\alpha 2^{NTD}$ interacts with β' . Each α^{NTD} is connected to its C-terminal domain (CTD) via a flexible linker (Fig. 2(A), top; α CTDs are not seen in the structure in Fig. 1). The small ω subunit interacts with β' . σ^{70} interacts extensively with core, primarily through a portion of R2 that interacts with a coiled-coil motif within β' , but in addition, σ R1.1 lies within what will be the downstream DNA channel, σ R3.2 follows the channel through which the synthesized RNA will extrude, and σ R4 interacts with a structure within β , called the β -flap. The very C-terminus of σ^{70} (σ^{CT}) interacts with the β -flap tip (Fig. 2(A)).

A competent transcription complex is formed when *E. coli* σ^{70} -RNAP interacts stably with promoter DNA (Fig. 2(A)). Promoter recognition arises through interactions with double-stranded (ds) portions of the promoter: σ R4.2 with the -35 element (consensus sequence -35TTGACA^{-30}) and σ R3.0/2.4 with the -15TGnT^{-12} motif, which includes the extended -10 sequence -15TG^{-14} and the first position of the -10 element (consensus -12TATAAT^{-7}). The α CTDs can also interact with ds UP elements, AT-rich sequences between -40 and -60 . However, not all of these elements are needed for recognition, and there are two main promoter classes: $-10/-35$ promoters (with matches to the -35 and -10 elements), and extended -10 promoters (with a good match to the -15TGnTATAAT^{-7} motif, but no recognizable -35 element). A single-stranded (ss) transcription bubble (from -11 to $+3$) is bound by σ R2.3, which interacts with specific sequences within the nontemplate strand (consensus -11ATAAT^{-7}), while the template strand is within the active site. Transcription initiation begins as ribonucleoside triphosphates enter the active site. The synthesized RNA exits through the RNA exit channel, a region that is filled by σ R3.2 within the holoenzyme (Fig. 1). Thus, RNA

RNAP: core ($\beta \beta' \alpha 1^{\text{NTD}} \alpha 2^{\text{NTD}} \omega$) + σ

Fig. 1 Structure of *E. coli* RNAP [PDB 4IGC] modeled with promoter DNA. RNAP core subunits β (light gray-blue), β' (dark blue), ω (magenta), $\alpha 1^{\text{NTD}}$ (teal), $\alpha 2^{\text{NTD}}$ (light cyan), the σ specificity subunit $\sigma 70$ (yellow), and ds promoter DNA (template strand, red; non-template strand, orange) are shown. (The α^{CTD} s are not observed in the structure). Features discussed in the text are indicated.

Fig. 2 Changes to *E. coli* RNAP as T4 infection proceeds. (A) Host RNAP used for T4 early transcription. (B) Host RNAP with T4 MotA and AsiA used for middle transcription. (C) Host RNAP with T4 gp33, gp55, and gp45 used for late transcription. In each case the schematic is shown above; for (A) and (B), structural models are shown below. RNAP core is designated in light gray, $\sigma 70$ in yellow, MotA in green, AsiA in dark gray, gp33 in Carolina blue, gp55 in purple and gp45 as the gray triangle. In the bottom panels, the positions of $\sigma 70$ R2, R3, and R4, α^{CTD} s, σ^{CT} , MotA (NTD, linker, and CTD), AsiA, and the promoter elements (-10 , -35) are shown.

extrusion destabilizes the interaction of σ with core, facilitating σ release. Typically, highly processive elongation continues until RNAP encounters an intrinsic termination signal, a stem-loop hairpin followed by a U-stretch, or a factor-dependent termination site, where the RNAP/DNA complex terminates, and RNAP dissociates from the DNA.

Developmental Pathways and Transcription Control by T7, T4, and N4

T4

Bacteriophage T4, a member of the Myoviridae family, does not encode its own RNAP. Instead it encodes factors that change the specificity of the host polymerase as infection proceeds, allowing it to program a temporal pattern of phage development from

early to middle to late promoters. In general, early proteins are needed for host takeover and middle transcription; middle proteins are needed for replication, for factors involved in late transcription, and for additional host takeover functions; and late proteins make up the virion structure. However, the functions of dozens of T4 genes, especially early, are still unknown.

Early promoters are active immediately after injection of the phage DNA. Host σ^{70} -RNAP is diverted to these promoters in two major ways: (1) early T4 promoters, which have near ideal matches to the consensus -35 and extended -10 sequence motifs, compete exceptionally well with host promoters for the available RNAP, and (2) modification of the RNAP by the T4 Alt protein, which is present in the phage head and is injected with the DNA, further increases the activity of early promoters relative to those of the host. Alt ADP-ribosylates one of the α subunits at R265, a residue that is needed for α CTD recognition of the UP element promoter motif (Fig. 2(A)). As approximately $\sim 70\%$ of transcription arises from the very strong host ribosomal promoters and UP element recognition contributes to ribosomal promoter strength, it is thought that this modification serves to immediately suppress a substantial amount of host transcription after T4 infection. It is not known which α is modified by Alt.

T4 early transcription leads to the expression of phage early genes. Two of these encode MotA, a DNA-binding transcription activator, and AsiA, a transcription co-activator, which are required for T4 middle promoter activation through a process called σ appropriation (Fig. 2(B)). This process, which starts about 1 min after infection, redirects RNAP to T4 middle promoters, which contain the σ^{70} -10 element and a MotA box motif [consensus sequence 5' (a/t)(a/t)(a/t)TGCTTA3'] centered at -30 . AsiA first binds to R4 of free σ^{70} to form a complex in which this portion of σ is completely restructured. Consequently, upon binding to core, σ is unable to bind the β -flap or to interact with the -35 element of σ^{70} -dependent promoters. (Curiously, the binding of AsiA does not appear to inhibit T4 early promoter activity). Importantly, σ^{CT} , which would normally be held by the β -flap tip (Fig. 2(A)), is now available for interaction with its binding partner, MotA^{NTD} (Fig. 2(B)). The MotA box motif within the middle promoter is engaged by the MotA^{CTD}, which binds to the downstream portion of the MotA box in the major groove while the MotA^{linker} (between the NTD and CTD) interacts with the upstream portion in the minor groove. The DNA binding motif of MotA^{CTD} represents a previously unrecognized way to interact with DNA – a double wing saddle structure in which both wings lie within the major groove. Overall the binding of AsiA and MotA serves to switch promoter recognition from a standard $-35/-10$ promoter to the middle MotA box/ -10 promoter.

In addition to activation of middle promoters, T4 middle genes are also expressed by the extension of early transcription from early genes into downstream middle genes. Although this extension requires T4 protein synthesis, no specific T4 product, such as an anti-terminator, has been identified. Rather it is thought that the process of translation itself serves to promote either transcription elongation and/or stabilizes the extended RNA.

All cytosines within the T4 genome are modified by the addition of a 5-hydroxymethylated, α - or β -glucosylated moiety, whose presence protects the phage DNA from *E. coli* and T4 nucleases. Although this modification is not required for T4 transcription, it does provide significant advantages for phage gene expression. In the case of σ appropriation, modeling of the modification within the MotA^{linker-CTD}/DNA crystal structure indicates that the glucosyl sugar will make significant contact with the MotA^{CTD} saddle. Binding analyses demonstrate that the presence of the 5'-hydroxymethyl, glucosyl moiety increases MotA affinity for the MotA box by > 100 -fold.

The T4 Alc protein also uses this modification to distinguish between host and phage DNA. Alc, a T4 early protein of 16.7 kDa, specifically promotes transcription termination of unmodified DNA. This function is thought to arise through an interaction of Alc with a nonconserved region of the β subunit of *E. coli* RNAP (Dispensable Region 1) near a residue (R368) that lies close to the RNAP active site (Fig. 1). Interestingly, Alc function requires rapidly elongating RNAP, consistent with the optimal conditions for T4 infection in rapidly growing cells.

The activation of middle promoters also results in middle products that severely disrupt host transcription. First, T4 nucleases, encoded by middle genes *denA* and *denB*, specifically degrade unmodified DNA, resulting in $\sim 50\%$ decrease in the host genome and effectively destroying the ability of the host to express its DNA. In addition, the T4 Mod protein completes the ADP-ribosylation of RNAP by modifying the other α subunit (again at residue 265). This modification then prevents any interaction of the α CTDs with UP elements, presumably further inhibiting host promoter activity.

About 5 min after infection at 37°C , T4 late promoters become active (Fig. 2(C)). These promoters are recognized by *E. coli* RNAP core together with two T4 middle products that together constitute a new σ factor: gp55 and gp33. Gp55, a distant member of the σ^{70} family, retains an R2 motif that interacts with the T4 late -10 promoter element, $^{-13}\text{TATAATA}^{-6}$. Gp33 bears no sequence resemblance to σ factors, but nevertheless interacts with the β -flap of core, just like σ^{70} R4. However, gp33 does not interact with the DNA, and late promoters do not have an upstream element like the -35 element of σ^{70} -dependent promoters. Thus, both middle and late T4 transcription involves employing a 'new' σ factor, either by reconfiguring σ^{70} with MotA and AsiA (middle) or replacing σ^{70} with gp55/gp33 (late).

Besides gp55/gp33, late promoter activation is also dependent on DNA replication. This connection stems from the requirement for gp45, a replication protein, called the 'sliding clamp' that can interact with either T4 DNA polymerase, gp33, or gp55. The structure of gp45 is a triangular donut, which encircles the dsDNA (Fig. 2(C)). Gp45 is loaded onto the DNA by the T4 clamp loader complex (gp44/gp62) and then moves along the DNA. During replication the interaction between gp45 and DNA polymerase 'clamps' the replication machinery onto the DNA, insuring processivity. However, the interaction between gp45 and gp33/gp55 allows RNAP to also move along the DNA, scanning for a late promoter. Consequently, gp45 behaves as a transcriptional enhancer that lacks a specific enhancer binding motif. The connection between late transcription and DNA replication allows the phage to produce an amount of virion assembly proteins that is consistent with the level of replicated phage DNA.

Besides gp33/gp55, other T4 middle products, RpbA and DsbA, bind to RNAP during late transcription. *In vitro* the presence of RpbA together with ADP-ribosylation of the α CTDs improves late promoter activity while diminishing middle promoter function. However, RpbA is not essential, and whether this is its function *in vivo* is not known. DsbA is a ~ 10 kDa protein that binds weakly upstream of some late promoters. Despite an early report that the presence of DsbA enhances transcription at these promoters, it is now reported that it has no effect on late transcription *in vitro*. However, the *dsbA* ORF overlaps the 3' end of gene 33, suggesting that translational coupling of these two genes could influence late transcription *in vivo*.

T7

Bacteriophage T7 is the prototype of the *Podoviridae*. The hallmark of this group is that most encode an RNAP that is responsible for transcription of most of the phage DNA.

The 40 kb T7 genome encodes Class I, Class II, and Class III genes (Fig. 3(A)). Class I genes are responsible for synthesis of the phage RNA polymerase and proteins required to protect the DNA from degradation (among other functions). Class II genes are largely involved in DNA replication and recombination. Class III genes encode proteins required for virion assembly, packaging of phage DNA, and lysis of the cell. All transcription proceeds unidirectionally, and only one strand of the DNA is transcribed. Initially, only the first ~ 850 bp of DNA is injected into the cell; the remainder is transported by transcription, first by the host RNAP and subsequently by the phage RNAP.

Early transcription

Transcription of the Class I genes by the host RNAP is initiated near the left end of the genome from a cluster of three strong promoters that have evolved to be optimal under different intracellular conditions (Fig. 3(A)). Termination occurs at the end of the early region at TE, which is similar to intrinsic terminators for *E. coli* RNAP and encodes an RNA with a potential stem-loop structure followed by a run of Us. The polycistronic early region transcript is processed by RNase III into individual mRNAs. Inhibition of transcription by the host RNAP involves the actions of gp0.7, a protein kinase that phosphorylates β' (as well as other host proteins), resulting in increased factor-dependent transcription termination, and by gp2, which binds to σ^{70} R1.1, preventing its movement from the downstream DNA channel (Fig. 1), thereby blocking initiation. In addition, nucleases encoded by gp3 and gp6 efficiently degrade the host genome; over 80% of phage DNA is derived from host DNA.

Phage RNAP and late gene transcription

T7 RNAP is related structurally and by sequence homology to other members of the Pol I family of nucleotide polymerases, which include DNA Pol I, reverse transcriptase, and mitochondrial RNA polymerase. A catalytic core domain is conserved within this class, while other regions are specific to the transcription functions of the enzyme. The preservation of the core among these varied polymerases, which utilize different templates and substrates, is remarkable; the relationship to mitochondrial RNAP is thought to reflect the origin of this organelle as an early prokaryotic symbiont of eukaryotic cells. The T7 RNAP consists of 883 amino acids (Figs. 3(B) and 4(A)). The 'cupped right hand' finger, thumb and palm subdomains, containing the catalytic core, are within the conserved C-terminal region while the N-terminal domain is involved in promoter recognition, elongation, and termination.

In addition to its role in transcription, the phage RNAP is involved in other essential functions, including transport of the phage DNA into the cell, priming of DNA replication, and maturation and packaging of the DNA.

Promoters for the phage RNAP are related to a consensus sequence that extends from -17 to $+6$, where initiation is at $+1$ (Fig. 3(C)). Whereas the class II promoters differ from the consensus at a number of positions, class III promoters preserve this sequence. Control of late transcription involves T7 lysozyme (Lys, gp3.5), a dual function protein that includes an amidase that is involved in cell lysis (in its C-terminal portion) and a separable regulatory function that is involved in modulating activity of the RNAP during initiation and pausing (in the N-terminal portion). The mechanism of action of Lys is unclear. Binding of Lys to the RNAP alters the configuration of the C-terminus of the T7 RNAP, which is in close proximity to the active site, and increases K_m for the initiating NTPs, suggesting that it may exert its effect by preferentially inhibiting initiation at the weaker class II promoters.

The transcription cycle

T7 RNAP goes through the same steps in the transcription cycle as the multi-subunit RNAPs. These include promoter binding and initiation, promoter clearance, elongation, and termination. Extensive genetic, biochemical, and structural analyses have provided insight as to how these steps occur in exquisite detail.

Promoter binding involves interaction of the upstream region of a promoter with elements in the N-terminal domain of the RNAP (e.g., the AT-rich recognition loop and the intercalating loop (β -IH)) and with the "specificity loop" (a beta hairpin that projects from the fingers subdomain in the C-terminal core). Meanwhile, the downstream region of the promoter, which includes the start site for initiation ($+1$), interacts with elements in the catalytic core domain. Binding of the polymerase is accompanied by bending of the promoter that results in strand separation ("melting") of the promoter from -4 to $+3$, exposing the template strand bases in the initiation region and allowing initiation and the incorporation of the first few nt into the nascent transcript.

The initiation complex (IC) can only accommodate up to three base pairs of the growing RNA:DNA hybrid. As the transcript is elongated from 3 to 7 bp, steric clash with the N-terminal domain results in a rotation of this domain as a rigid body by about 40 degrees, without promoter release. The resulting strain in the complex can lead to release of abortive initiation products before the

Fig. 3 T7 transcription. (A) Transcription map of T7. All transcription is from left to right. Locations of promoters and the direction of transcription for host (green) and phage (red, blue) RNAPs are indicated by arrows. Termination/pause signals are denoted by vertical bars. The primary origin of DNA replication (ori) is indicated. The genetic and physical maps are at the bottom; not all genes are identified in this figure. (B) Structural changes that occur during the transition from IC (PDB 1QLN) to an EC (PDB 1MSW). The two structures are oriented similarly with regard to subdomains in the catalytic C-terminal core: palm (red), fingers (blue), and thumb (green). The N-terminal domain is in gray. Elements involved in upstream promoter recognition include the specificity loop (purple), the AT-rich recognition loop (cyan), and β -IH, the intercalation loop (yellow). (C) Consensus promoter sequence for T7 RNAP. Key elements of the RNAP that interact with the binding and initiation regions of the promoter are indicated. The region that is melted open during promoter binding is indicated by displaced template (bottom) and non-template (top) strands of the DNA. The initiation site is at +1.

Fig. 4 Comparison of the structures of the single-subunit RNAPs encoded by T7 and N4 complexed with DNA. (A) T7 RNAP (PDB 1CEZ). (B) N4 mini-vRNAP (PDB 3C3L). (C) N4 RNAP II (PDB 6DT7). In each case, the right ‘cupped hand’ composed of fingers (dark blue), palm (red), and thumb (green), the AT-recognition loop (cyan), the specificity loop (purple), and the β -IH (“intercalation loop”, yellow) are shown. DNA is shown in orange with position -1 indicated as a sphere.

transition to a stable elongation complex (EC) occurs. Notably, as the length of the transcript approaches ~ 8 nt (the length of the hybrid in the EC), the 5' end of the RNA comes into contact with the specificity loop, which is involved in upstream promoter contacts. This is reminiscent of the situation with *E. coli* RNAP in which the lengthening transcript displaces σ R3.2 (see above), suggesting that such interactions may be a common feature of promoter release. Beyond this point (after synthesis of 9–12 nt), release of promoter contacts occurs, and is accompanied by major conformational changes that result in the formation of an RNA exit tunnel, and a stable EC (**Fig. 3(B)**).

Elongation

Once the complex has isomerized into the EC, it is highly stable and will transcribe many kb of template without dissociation until it encounters a pause or a termination signal. Each cycle of nucleotide addition is accompanied by opening and closing of the active site in the catalytic core, and translocation of the EC along the template. Recognition of the next incoming nucleotide occurs in the “open” state by the formation of a nascent base-pair with the exposed template strand base. Closing of the active site places the incoming nucleotide and template base in a position that is suitable for catalysis. Formation of the phosphodiester bond results in the release of PP_i, which destabilizes the closed complex, triggering a return to the open complex and translocation of the EC to the next position along the template.

Termination

T7 RNAP pauses or terminates at two types of signals. The termination signal $T\phi$, located downstream of gene 10, resembles intrinsic terminators for *E. coli* RNAP such as TE, but has a longer stem-loop structure and a longer run of U residues downstream. Termination at this site is not complete, and read through transcription is required for expression of genes 11 and 12. The mechanism of termination at $T\phi$ is not clear, but may involve steric clash of the stem-loop structure with the RNA exit pore, and/or induced slippage of the transcript at the run of U residues, resulting in misalignment in the active site.

A second type of signal is present in the junction of replicating T7 DNA concatemers (CJ). This signal does not encode an RNA with secondary structure but involves recognition of a specific sequence (TATCTGTT) and results in pausing rather than termination. The efficiency and duration of the pause is dramatically increased in the presence of T7 Lys, and the halted complex is thought to recruit other phage proteins that are involved in processing and packaging of the DNA. The mechanism of pausing is not clear, but is likely to involve recognition and binding of the signal in the nontemplate strand. This feature may be a common mechanism for pausing/termination, as *E. coli* RNAP has also been found to recognize pause sites in this strand.

N4

The lytic podoviridae phage N4 employs the host multi-subunit RNAP and 2 phage-encoded RNAPs, both of which are distantly related to the T7 family of single-subunit RNAPs. Expression of early N4 genes depends upon a virion-encapsulated RNAP (vRNAP) that is injected into the host upon infection. This injection results in the entry of the first 500 bp of the left end of the linear N4 DNA. The DNA is then constrained/supercoiled by the action of host gyrase to generate a template that extrudes hairpins on the template and non-template strands at three vRNAP promoter sequences. Binding of the *E. coli* single-stranded binding protein (Eco SSB) generates a single-stranded (ss) non-template strand and stabilizes the template strand hairpin, which is recognized through the interaction of vRNAP with bases -11 , -10 , -8 , and $+1$. Thus, Eco SSB has been described as an ‘architectural transcription factor’. Once transcription initiates, Eco SSB also binds the exiting transcript. vRNAP lacks a domain present in T7 RNAP, which binds RNA, separating it from the template. Consequently, it is thought that the Eco SSB/transcript interaction serves to replace this function.

Despite the large size of vRNAP (3500 aa), only 1/3 of the protein (1106 aa) is required for transcription. Structural analyses indicate that this mini-vRNAP shares common structural features of the ‘cupped right hand’ single-subunit RNAPs (**Fig. 4(B)**). This structural similarity exists despite practically no sequence homology. In both vRNAP and T7 RNAP (**Fig. 4(A)**), the DNA is recognized similarly: a specificity loop interacts with the major groove of the ds DNA (the hairpin in the case of vRNAP promoters), the β -IH (intercalating loop) recognizes the ds/ss DNA junction present at the upstream edge of the transcription bubble, and the upstream recognition element recognizes position –11 in the N4 promoter or the upstream AT-rich region of a T7 promoter (**Figs. 3(C)** and **4**).

Once the N4 early genes are transcribed, the remaining portion of the N4 genome is injected and middle gene transcription commences. Middle transcription requires a second N4 RNAP, RNAP II, encoded by genes 15 and 16. Like vRNAP, RNAP II is a minimal, T7-like RNAP (**Fig. 4(C)**). It bears much structural and some sequence homology to the T7 protein. RNAP II associates tightly with the cytoplasmic membrane, and transcription requires either denatured DNA or a membrane-bound DNA containing the N4 ssDNA binding protein, gp2. While either substrate is active, only the gp2/membrane/DNA substrate results in specific transcription. It has been proposed that another N4 protein, perhaps gp1, denatures the promoter region, which then allows gp2 to bind and recruit RNAP II.

In a perverse twist, N4 late transcription, which generates the RNAs needed for the production of morphological proteins, requires the host RNAP. Besides host σ^{70} -RNAP, late transcription also requires a middle gene product, the N4 SSB protein. Although N4 SSB is required for N4 replication, a distinct region of the protein at the C-terminus interacts with the β' subunit of RNAP. Thus, as in T4 late transcription, a part of the N4 late transcriptional machinery is directly connected to DNA replication.

Inhibition of Host RNAP by T4, T7, and N4, and Other Members of Those Families

As detailed above for T4 and T7, phages produce products to eliminate or down-regulate transcription by the host RNAP. Recent work has identified novel phage inhibitors. Xp10, a Siphoviridae phage of the plant pathogen *Xanthomonas oryzae*, encodes a protein (p7), which both inhibits recognition of host –10/–35 promoters and functions as an antiterminator at intrinsic (factor-independent) termination sites. This results in efficient transcription from the phage extended –10 promoters while host transcription is inhibited. The primary binding site of p7 is the N-terminus of the β' subunit (**Fig. 1**), but the β -flap domain and the ω subunit, have also been implicated in transcription inhibition and anti-termination, respectively.

The *Thermus thermophilus* phage P23–45 produces two inhibitors of *T. thermophilus* RNAP, gp76 (an early gene product) and gp39 (a middle gene product). Gp76 interacts with the downstream DNA channel of RNAP (**Fig. 1**) and the path that would be occupied by the upstream portion of the ss template strand (–11 to –4) within the transcription bubble. Gp39 binds to the β -flap and σ R4, thus interfering with the σ R4/ β -flap interaction needed for –10/–35 promoter activity. This facilitates phage promoter activity since P23–45 middle and late promoters belong to the extended –10 class.

Finally, gp67 of G1, a Myoviridae phage that infects *Staphylococcus aureus*, inhibits the host by yet another mechanism. In this case, gp67 binds to σ R4, but this binding does not interfere with its ability to recognize the –35 element. Instead this binding allows gp67 to interfere with α CTD binding to UP elements between –40 and –60. Since the strong ribosomal promoters rely on α CTD/UP element interaction and ribosomal transcription accounts for the majority of overall bacterial transcription, this inhibition leads to a major down-regulation of transcription in the host.

Summary

Despite their relatively small genomes, lytic phages employ highly sophisticated and varied strategies to maximize transcription of their own DNA while limiting host gene transcription. Understanding these processes at a molecular level has deepened our understanding of transcription mechanisms used by both multi-subunit and single subunit (Pol I-like) RNAPs. In particular, phages are providing a rich resource for studies of RNAP inhibitors. Interest in the detailed mechanisms of these inhibitors has surged in recent years as researchers search for ways to combat emerging and reemerging bacterial pathogens. It is likely that a vast array of other mechanisms will be discovered as new phage functions are identified.

Glossary

Lysogen A bacterial cell carrying one or more bacteriophage genomes, either integrated into the host chromosome or existing as independently replicating extra-chromosomal elements. A true lysogen is able to exit lysogeny and re-enter lytic development.

Lysogenic conversion The situation where a bacterial host acquires a new trait as a direct result of the expression of a gene or genes encoded by a prophage.

Prophage The lysogenic form of a bacteriophage.

Prophage induction The process of a bacteriophage exiting lysogeny and entering lytic development, resulting in lysis of the host cell.

Temperate bacteriophage A bacteriophage capable of entering either lytic development or lysogeny upon host cell infection.

Terminally redundant DNA DNA that contains repeated sequences at each end called terminal repeats. These ends are used to join the ends of the linear DNA to form circular DNA.

Transcriptional interference The suppressive influence of one transcriptional process, directly and *in cis* on a second transcriptional process.

Introduction

Bacteriophages (phages) are obligate bacterial parasites. Many phages exhibit a purely lytic lifecycle, where following infection of a susceptible host, the phage DNA is replicated and the phage hijacks the bacterium's cellular machinery to produce new virion particles, which are released upon lysis of the host cell. Other phages, the so-called temperate phages, are able to make a developmental 'decision' between two developmental regimes, the lytic and lysogenic cycles. In lysogeny, the phage persists indefinitely inside the bacterial host as a prophage, with the phage genome either integrated into the bacterial chromosome or existing extra-chromosomally (Fig. 1). Lysogeny is a non-bacteriocidal state where the bacteriophage genome replicates without virion production. In this state, most of the phage genome is transcriptionally inactive, as the expression of lytic functions would be lethal to the host cell. A bacterial host cell lysogenic for a particular phage is also immune to further infection by the same phage.

Filamentous phage, which have ssDNA genomes packaged into filament-like virions, are able to replicate without killing the host. Among the filamentous phage, some integrate in the host chromosome, while non-integrative filamentous phage replicate exclusively as extrachromosomal elements or episomes. Both classes of filamentous phages continually shed viral particles without host cell death, even while inserted into the bacterial genome as a prophage. Thus, bacteria infected permanently with filamentous phage represent a form of lysogeny, but don't meet the definition of true temperate phage, in that there is no stage which brings about host cell lysis.

In this article, we discuss specific examples of how true temperate phage establish and maintain lysogeny. The phenotypic effects of lysogeny on the host bacterium and the evolutionary impacts of lysogeny are also discussed.

Why Lysogeny?

For a phage to successfully propagate, it must coax its host into manufacturing new virions. These new virions are released through host cell lysis, and need to infect another host bacterium in order for the phage to continue to propagate. From the phage perspective, during times of abundant resources and the presence of many host cells, lytic development allows for large numbers of phages to be produced, to subsequently infect other host cells and thus continue the cycle. However, when resources and/or susceptible host cells are scarce, the phage can benefit from entering lysogeny until conditions improve. The process of making a choice between the lytic and lysogenic pathways following host cell infection, is covered in more detail in another article (Golding). While there must be some (small) fitness cost in replicating extra genomic material, many phages have evolved such that lysogeny can provide a selective advantage to the host cell in a number of ways. Such benefits may include carrying genes which confer some growth advantage to the host, or by providing protection from subsequent infection, and potential lysis, by phage from the same or different families.

Persistence of DNA

Integration Into the Chromosome

The long term persistence of phage DNA inside their bacterial host cell is the key feature of a lysogen. Phage have evolved many mechanisms to achieve this long term persistence. In many cases, such as the paradigm bacteriophage λ , the phage DNA is

Fig. 1 Lytic and lysogenic developmental cycles of a temperate bacteriophage. A bacteriophage infects a bacterial host by injecting its DNA (red) into the host cell. In the lytic lifecycle, phages produce new virions, lysing the cell to release them. The lysogenic lifecycle has the phage DNA integrated into the bacterial chromosome or persisting extra-chromosomally. This state is stable, with prophage DNA maintained in daughter cells over subsequent generations. Most temperate phage can efficiently exit lysogeny to reenter the lytic phase in response to specific environmental cues.

integrated into the bacterial chromosome via site-specific recombination (**Fig. 2**). The phage-encoded integrase protein is a site-specific recombinase that recognizes attachment (*att*) sites on both the phage genome (*attP*) and the bacterial chromosome (*attB*). The integrase catalyses recombination between the *attP* and *attB* sites. This process generates two new *att* sites, *attL* and *attR* that flank the phage genome. When the phage exits lysogeny, the excision machinery, consisting of at least the integrase and a phage-encoded recombination directionality factor (RDF), and often with additional host factors, recognizes the *attL* and *attR* sequences to catalyse the reverse reaction to excise the prophage genome.

In general, integrase proteins belong to one of two families, the serine integrases or the tyrosine integrases. These proteins use a catalytic serine or tyrosine, respectively, to carry out the recombination reaction. Serine integrases create a double stranded break in both the phage and bacterial chromosome, and mediate strand rearrangement to bring them into the recombinant configuration, followed by strand ligation. Tyrosine recombinases, on the other hand, mediate recombination via a Holliday junction intermediate. Single stranded cuts are made in DNA and rejoined to single stranded DNA from the recombinant partner. Both types of integrases have been used extensively for biotechnology and molecular biology applications.

Some temperate phage integrate their DNA less specifically into the bacterial genome. Upon infection of a host cell, phage Mu initially integrates at random into the host chromosome. Only after integration is a decision on lytic or lysogenic development made. If the lytic pathway is followed, the phage genome undergoes successive rounds of replicative transposition. In each round, Mu DNA is duplicated, and a range of host genome rearrangements (deletions, inversions, translocations) are introduced. Viral genomes, along with variably sized segments of the host genome, are packaged directly from the integrated copies dispersed around the scrambled host genome. Similar to other temperate phages, the Mu lysogenic pathway (termed the latent pathway in Mu) is followed if the Repc repressor protein accumulates to a sufficiently high concentration. Repc competes for overlapping operators with DDE-recombinase A, which binds to an internal activation sequence (IAS), to initiate the lytic pathway.

In Mu, the initial integration process occurs by random transposition (**Fig. 3**). This process utilizes transposition machinery consisting of phage-encoded and host-supplied components to cleave the Mu DNA and insert it into target sites in the host genome with little or no target specificity. When Mu injects its DNA into a new host cell, its DNA is linear and flanked by DNA that was acquired from the previous host from which it was assembled. The phage supplied N protein, injected alongside DNA, non-covalently circularizes the DNA. To integrate Mu DNA into the chromosome, the phage DNA is nicked by MuA transposase to generate two 3' hydroxyl (-OH) ends on both strands at the Mu-Host DNA junctions. The 3'-OH ends attack two phosphodiester bonds spaced 5 bps apart, which join the 3'-OH to the 5' phosphate of the host DNA at the attack site. The flanking segments of DNA from the previous host are removed and the DNA gap is repaired.

A natural consequence of phage DNA integration into the host chromosome is that host DNA replication will also replicate the prophage DNA. Thus, all daughter cells of a lysogen will inherit the prophage. This form of lysogeny can be extremely stable, with very low rates of 'spontaneous' induction.

Fig. 2 Prophage DNA can be maintained by site-specific integration into the bacterial chromosome. This reaction is mediated by a phage-encoded integrase protein (Int). Initially upon injection into the host, the phage DNA is linear. Circularization of the viral DNA occurs through annealing of complementary ends, followed by ligation. Integrases recognize the attachment sites *attP* on the viral DNA (dark green) and *attB* on the host chromosome (light green) to catalyse the site-specific recombination. This generates two new *att* sites, *attL* and *attR* which flank the viral DNA in the chromosome. The attachment sites have a conserved core, shown in black. To return to the lytic cycle, the viral DNA must be excised from the chromosome through a reversal of the site-specific recombination between *attL* and *attR*, mediated by the excision machinery, which include the Int and excisionase (or recombination directionality factor RDF) proteins.

Extrachromosomal Persistence of DNA

Some prophages can also maintain their DNA separate from the host chromosome as a plasmid, either circular or linear. A well-characterized example of a circular extrachromosomal lysogen is bacteriophage P1. Infectious particles of P1 consist of a large (93 kb) linear double stranded genome with terminal redundancy of 10–15 kb. Upon being injected into the P1 host *E. coli*, the ends of the DNA undergo homologous recombination to circularize into an autonomous plasmid. In lysogeny, the prophage/plasmid copy number is maintained to be the same as the number of bacterial chromosomes. This is achieved through the expression of P1 proteins involved in origin-specific initiation and partitioning. The phage also uses a toxin-antitoxin system to kill daughter cells that have failed to receive a P1 molecule upon cell division. The antitoxin is degraded rapidly and needs to be continually expressed to counteract the toxin's activity. Loss of the P1 molecule in daughter cells results in a rapid depletion of antitoxin to a level where the more stable toxin will kill the host cell.

Some prophages, such as *E. coli* bacteriophage N15 maintain their DNA as a linear plasmid. Similar to linear eukaryotic chromosomes, this presents a problem as DNA polymerase fails to replicate all the way to the ends of the DNA. Bacteriophage N15 belongs to a group of phages that express a protelomerase to create covalently closed hairpins. After entering the cell, N15 DNA circularizes through its cohesive termini. The phage encoded protelomerase cuts an inverted sequence in the phage genome and ligates the phosphodiester bonds of each strand to form two closed hairpin ends (Fig. 4).

The replication of such as linear plasmid also presents mechanistic challenges and requires prophage encoded proteins. In the case of bacteriophage N15, the phage repA protein is necessary for replication. This multi-domain protein contains domains that resemble prokaryotic primases and helicases required for DNA replication.

Fig. 3 Bacteriophage Mu integrates into the *E. coli* chromosome via random transposition. Linear Mu DNA is non-covalently circularized via the N protein. The Mu B transposase generates single stranded nicks at the junctions of the Mu (blue)-prior host DNA (red) sequence, revealing two 3'-OH ends. These ends attack a target site on the *E. coli* chromosome to join the 3'-OH of Mu DNA to the 5' phosphate of the host DNA. Removal of the prior host DNA and subsequent repair of the DNA gap at the host-Mu DNA junction via limited replication results in successful integration of Mu into the chromosome.

Maintenance of the Lysogenic State

Temperate phages often contain natural examples of genetic switches which enable the developmental choice between the lytic or lysogenic lifecycles. The biochemical basis of this decision-making process will be covered in detail in a separate chapter of the encyclopedia. After entering lysogeny, true lysogens are able to exit back into the lytic cycle, either spontaneously or in response to environmental cues. One strategy to generate such a bistable decision making circuit is through mutually repressing transcription factors. The most well characterized bacteriophage employing this strategy is bacteriophage λ .

Fig. 4 A prophage of bacteriophage N15 maintains its DNA as a linear plasmid with closed hairpin loops. Upon injecting its DNA into *E. coli*, the phage initially circularizes through the annealing of complementary ends. A phage encoded protelomerase binds and cleaves an inverted repeat sequence (*telRL*) within the genome. The phosphodiester backbone of single strands are then ligated together to form two hairpin loops, creating one covalently closed DNA molecule. Linear plasmid replication requires a phage encoded protein, *repA*.

Bacteriophage λ

The bistable regulatory circuit in λ is generated by the CI and Cro repressors, which block each other's transcription. To maintain lysogeny, the promoters that drive lytic functions must be repressed, whilst maintaining production of the CI repressor. In general, the repressor in temperate phages responsible for turning off lytic function is termed the immunity repressor, as it prevents secondary infections by phage of the same family, by blocking the lytic functions of incoming phage.

λ has a lysogenic promoter, P_{RM} , positioned back to back with the adjacent lytic promoter P_R , with a second lytic promoter, P_L located 2.3 kb away (Fig. 5). The transcriptional cascade in λ is such that repression of the early lytic promoters P_L and P_R will stop all of the lytic genes from being expressed, pushing the phage into lysogeny. This repression is achieved by the λ CI protein, which binds to operators at O_R and O_L operators that overlap the P_R and P_L promoters, respectively. In the lysogenic state, CI simultaneously represses transcription from P_L and P_R , while activating its own expression from P_{RM} .

The lambda CI protein is a two domain protein consisting of an N-terminal DNA binding domain connected by a cleavable linker to an oligomerization domain. The repressor homodimerizes and these dimers can bind to individual operators. However, repressor binding is cooperative such that pairs of dimers bound to adjacent operators (primarily O_{R1} - O_{R2} and O_{L1} - O_{R2}) interact to improve overall binding affinity. In this state, P_R and P_L are repressed, whilst P_{RM} is activated by a contact between the CI dimer bound at O_{R2} and the σ subunit of RNA polymerase. In this manner, λ CI produces positive feedback to increase its own expression. A further level of cooperativity also occurs, when a pair of dimers occupying two operators at O_R interact with a pair of dimers bound at O_L to form a CI octamer, looping out the intervening ~ 2.3 kb of DNA (Fig. 5). Octamer formation in turn positions the O_{L3} and O_{R3} operators to allow λ CI dimers bound at each of these sites to interact and repress P_{RM} at high levels of λ CI. This negative autoregulation is thought to limit the repressor levels to allow for efficient prophage induction back into lytic cycle (Fig. 5(D)).

Cro is the second transcriptional regulator within the lambda genetic switch. The *cro* gene is the first of the early genes expressed from P_R following phage infection, and is required to enforce prophage induction – the decision point when the phage switches from lysogeny towards lysis. Upon activation of the host SOS response, the CI repressor is degraded by a mechanism involving activated RecA improving an intrinsic but normally weak CI self-cleavage activity. Thus the lytic repressors are at least partially de-repressed and Cro is made. Cro binds as a dimer to the same O_L and O_R operators as CI, but with different affinity, binding most strongly to O_{R3} at the O_R operator. This preferential and non-cooperative binding to O_{R3} dampens CI expression from the P_{RM} promoter, while leaving the P_L and P_R promoters active. Thus, Cro repression of P_{RM} is required to prevent re-synthesis of new CI during prophage induction, which would otherwise re-establish the prophage state.

Fig. 5 Regulation of the λ lytic and lysogenic promoters by λ CI involves cooperative interactions at multiple levels. A. The arrangement of early lytic and lysogenic promoters in bacteriophage λ . The regulation of these promoters is crucial in the lytic-lysogeny decision. Promoters are depicted as bent arrows. RNA transcripts from P_L and P_R are shown in yellow. OL and OR operators are depicted as red bars on the DNA. B. λ CI (depicted as red dumbbells) binds to operators at OL and OR. λ CI dimers at adjacent operators can further interact to form tetramers, mediated through the CI C-terminal domain. Binding of λ CI blocks transcription from P_R and P_L , by blocking RNA polymerase (RNAP) binding. Contacts between the N-terminal domain of CI at O_{R2} and the sigma subunit of RNAP activates the P_{RM} promoter to drive expression of λ CI and other lysogenic functions. The lysogenic transcript from P_{RM} is depicted in green. C. The repression of P_R and P_L is further enhanced by interactions between CI tetramers at OR and OL, assisted by DNA looping. D. Formation of the CI octamer allows CI dimers bound at OL3 and OR3 interact cooperatively, to repress P_{RM} and downregulate CI's own expression.

Bacteriophage 186

Bacteriophage 186 is a temperate bacteriophage of the P2 related family, a group of phages evolutionarily distinct from the lambdoid phages. 186 and lambda infect the same host (*E. coli*) and have very similar temperate lifecycles, yet the mechanisms by which these two phages enter and maintain lysogeny are quite different. In 186, early lytic p_R and lysogenic promoters p_L are in a convergent arrangement (Fig. 6), rather than divergent as is the case for the λ P_R and P_{RM} promoters. A consequence of this convergent layout is that RNA polymerases either bound at, or elongating from, the switch promoters can potentially collide with each other. In the absence of the immunity repressor (CI), transcription from the stronger lytic p_R promoter represses transcription from the weaker lysogenic promoter p_L by this mechanism of transcriptional interference (TI), favouring the lytic lifecycle. Conversely, in the presence of CI, p_R is efficiently repressed, relieving transcriptional interference, and providing a form of positive feedback on CI expression.

A. Bacteriophage 186 switch region

B. DNA wrapping and looping by 186 CI

Fig. 6 Relief of transcriptional interference is used to activate transcription of lysogenic promoters in bacteriophage 186. A. The early lytic promoter pR and the lysogenic promoter pL are arranged face-to-face. CI is the 186 immunity repressor. Apl acts as both a repressor of the pR and pL promoters, and also as the excisionase for phage 186. The 186 CI repressor binding sites are drawn as circles – there are three strong sites (red) over the pR promoter, a weak operator located over pL (pink) and two distant sites (FL and FR), located ~300 bp from pR. B. Model of transcriptional activation of 186 pL by 186 CI. CI is shown as a wheel-like structure where DNA wraps around the circumference of the wheel. CI operators are shown as circles. The weak operator at pL is sometimes wrapped to the wheel (left) thus repressing pL, in an equilibrium with a form (middle) where the pL operator is not bound, allowing pL to be active. The flanking sites FL and FR can compete with pL for binding to the CI wheel (right), fine tuning the response of the system to CI levels.

The 186 CI protein is the immunity repressor responsible for maintenance of lysogeny. Similarly to λ CI, it contains an N-terminal DNA binding domain and a C-terminal oligomerization domain and binds to its operators as a dimer. Crystal structures suggest 186 CI forms a wheel consisting of a heptamer of dimers. The repressor's DNA binding domains face outwards from this wheel, allowing DNA to wrap around the protein (**Fig. 6(B)**) to regulate transcription of pR and pL. The CI wheel binds cooperatively to the three strong operators to repress pR and relieve transcriptional interference on pL. Binding of the weaker CI operator at pL to the CI wheel is in an equilibrium between wrapped (repressed) and unwrapped (active) forms. There is further fine tuning of pL promoter activity by the two flanking CI operator sites (FL and FR, located ~300 bp away) which can loop to the wheel and displace pL from the wheel. When the CI operator at pL is displaced by either of the stronger flanking site operators, pL is transcriptionally active, maintaining CI levels. Interestingly, in phage 186, integrase is also expressed on the lysogenic transcript, such that integrase is continually present in a lysogen. When prophage induction is triggered, excision of the phage genome requires only expression of the excisionase (Apl), the first gene of the lytic transcript.

Thus, phage 186 CI repressor maintains an active lysogenic promoter by relieving transcriptional interference on pL, to drive its own expression and to maintain a stable, self-correcting lysogenic level of CI. The lytic pR promoter is tightly repressed in this state, leading to low levels of spontaneous induction.

Integration-Dependent Bacteriophage Immunity

A class of temperate mycobacteriophage have been described which use site-specific integration as the key decision point of the genetic switch. In these phage, the immunity repressor and integrase are expressed from the same promoter P_{rep} . To the right of the repressor gene, under the control of a separate divergent promoter, P_R , is a Cro-like protein. Both the immunity repressor and Cro-like protein are predicted to have a DNA-binding helix-turn-helix (HTH) motif. Crucially, the bacteriophage attachment site *attP* is located within the open reading frame of the immunity repressor (**Fig. 7**).

Unlike bacteriophages λ and 186, the promoter driving the immunity repressor function is not regulated by the immunity repressor. Rather, the key step needed to establish lysogeny is the integration of the phage DNA into the host chromosome. Integration of the phage genome through recombination of *attP* and *attB* sites results in a truncated immunity repressor without a short destabilizing C-terminal tag. This truncated repressor supplies sufficient repression activity to establish lysogeny. The tag, thought to target the viral repressor for degradation by host proteases, reduces its effective activity below the level required for lysogeny.

The determining factor of the phage's developmental fate is the stability of the integrase protein. If conditions favor high integrase activity, such as high multiplicity of infection (MOI) or when host protease levels are low, integration of the phage genome is favored. Integration subsequently establishes and maintains lysogeny via immunity repressor stabilization.

Use of a Host Protein as an Immunity Repressor

In most phages, a phage-encoded immunity repressor binds to promoters that drive lytic functions to repress them. GIL01, a phage that infects *Bacillus thuringiensis*, is an interesting example of a phage that does not have encode an immunity repressor at all. It instead uses the *B. thuringiensis* host LexA repressor as its immunity repressor.

Fig. 7 The organization of integrase (*int*), immunity repressor (*rep*) and *cro*-like protein (*cro*) genes in integration-dependent immunity systems. Promoters are shown as bent arrows. Site-specific attachment sites are shown as green boxes. The *attP* attachment site lies within the *rep* open reading frame. Site specific recombination of *attP* with *attB* results in a truncated repressor gene within the bacterial chromosome. This truncated gene encodes for a more stable immunity repressor, driving the phage towards lysogeny.

It has been shown that the DNA binding activity of LexA in *B. thuringiensis* is regulated by GIL01 phage encoded proteins. When complexed with specific phage proteins, LexA represses lytic promoters by binding to a conserved LexA site within the promoter region. If these additional phage proteins are not expressed, LexA binding alone is too weak to repress the lytic promoter and GIL01 is unable to form stable lysogens.

RNA to Maintain Lysogeny

The mechanisms of maintenance of lysogeny that have been described thus far have been based on proteins, responsible for mediating either repression or integration. However, there are also examples of phage which use RNA-based mechanisms to maintain a stable lysogenic state.

Lactobacillus casei phage A2 has a similar genetic arrangement to that of the *O_R* region of lambda, with back-to-back promoters driving expression of CI and Cro repressors. However, in phage A2, the CI and Cro repressors have very similar affinities for their operators, leading to the expectation that the much stronger lytic pR promoter should dominate, leading to expression of Cro, and favoring the lytic cycle. However, A2 is able to effectively establish and maintain stable lysogens. It has recently been shown that the second gene of the A2 lytic transcript encodes an RNA binding protein (gp25) that is able to specifically bind to a region between the ribosome binding site and *cro* start codon on the lytic transcript. RNA binding by gp25 thus prevents translation of Cro, allowing establishment and maintenance of stable lysogens.

P4 is a so-called satellite phage that relies on an unrelated helper phage, such as P2 or 186, to supply the structural genes needed for its propagation. P4 has the ability to redirect the genetic network of the helper phage in order to redirect the capsid assembly process for its own purposes. The P4 replicon can exist as a plasmid or can be stably integrated into the host chromosome as a lysogen. The integrated lysogenic form is maintained by an RNA-based mechanism. In a P4 lysogen, transcription from a constitutive early promoter generates a ~300 nucleotide transcript that is processed to form the CI RNA. The CI RNA interacts with two specific regions in the untranslated leader sequence of the nascent transcript to mediate transcriptional termination, prevent expression of the P4 replication functions and thus, maintain lysogeny.

Prophage Induction

Established lysogens are generally stable with low probabilities of reverting back to the lytic state. Certain environmental stresses can stimulate the prophage to revert to the lytic state. This process is called prophage induction. The immunity repressor must be degraded or otherwise inactivated during prophage induction in order to establish lytic gene expression.

Many temperate phages are inducible by DNA damage, such as through mitomycin C treatment or UV irradiation. Such DNA damage results in activation of the host SOS response, a global cascade of gene expression centered on DNA repair. As explained previously, the stress response genes are under the control of the host LexA protein. LexA contains a labile linker region that can be cleaved by a C-terminal protease domain within LexA itself. In the SOS response, the activation of co-protease RecA as a result of the accumulation of single stranded DNA, promotes the auto-proteolysis of the host LexA repressor. Phage GIL01, which relies on LexA to directly repress lytic genes, will undergo prophage induction simply due to the removal of LexA. Some phage repressors, such as λ CI repressor, have structural similarity to LexA, and undergo similar RecA-stimulated self-cleavage. Inactivation of CI allows the expression of lytic genes, including the genes for excision and replication.

Other phages, such as bacteriophage 186, express specific anti-repressor proteins, which complex with their cognate repressor to relieve repression of the lytic genes. For example, bacteriophage 186 expresses the anti-repressor Tum, which is in turn under the control of a LexA repressible promoter. Upon activation of the SOS response, RecA mediated proteolysis of LexA results in expression of the Tum anti-repressor, which inactivates 186 CI, to drive prophage induction. The related coliphage P2 does not code for an anti-repressor, and does not induce in response to DNA damage. However, it has a somewhat higher level of spontaneous induction than 186, which must be sufficient for it to sustain a viable number of free phage.

The satellite phage P4, which uses an RNA based transcriptional termination mechanism for maintaining lysogeny, is induced by transcription from an alternative promoter activated by a protein from the helper phage. Translation of nested genes within this longer transcript leads to suppression of the CI RNA mediated termination, and expression of the P4 genes needed for replication.

Evolutionary and Phenotypical Effects of Lysogeny

It is estimated that the number of phage outnumber bacteria in the biosphere by at least an order of magnitude. Thus, it is unsurprising that phages have a large effect on the evolution of their hosts and play a significant role in shaping bacterial communities in almost all ecosystems. Here, we discuss how lysogeny has altered the phenotype and evolution of its hosts.

Lysogenic Conversion

Lysogenic conversion describes the situation where a bacterial host acquires a new trait as a direct result of the expression a gene encoded by a lysogen. Clinically relevant examples include the acquisition of virulence factors by bacterial pathogens. Many of the toxins contributing to virulence in bacteria such as *Staphylococcus aureus*, *Shigella* spp., *Salmonella enterica* and pathogenic *E. coli* have been acquired through lysogenic conversion. *E. coli* O157:H7, a causative agent of food poisoning, harbors Sp5 and Sp15 – two Shiga toxin expressing prophages. *Vibrio cholera*, some strains of which cause Asiatic cholera, acquired the cholera toxin from its CTX ϕ prophage.

Besides toxins, other phage-encoded virulence factors include adhesion factors, superantigens and factors that aid immune system invasion. Various examples of phage-encoded virulence factors are summarized in [Table 1](#).

In many cases, the virulence genes are arranged as a cassette flanked by a σ^{70} promoter on one side and a transcription terminator on the other. Such a configuration reduces interference with the prophage genes adjacent to the cassette. It has been postulated that virulence genes confer some fitness advantage to their host, either offensive (e.g., toxin production, invasins), defensive (e.g., detoxification) or survival (such as improved nutrient uptake).

Very recently, a type of temperate filamentous bacteriophage that infects and integrates into *Pseudomonas aeruginosa* (*Pa*) was found to be associated with chronic human wound infections. In mice, phage-infected *Pseudomonas aeruginosa* led to more severe and longer-lasting wounds compared to wounds colonized by *Pa* alone. The authors showed that uptake of phage-infected *Pseudomonas aeruginosa* by cells of the immune system resulted in phage RNA production, inappropriate antiviral immune responses and suppression of bacterial clearance.

Gene Disruption

Prophage integration into the host chromosome can alter bacterial phenotype by disruption of an open reading frame. The integration of phage may also disrupt sequences with regulatory roles within an intergenic region, altering how downstream genes are regulated. Prominent loci for *attB* phage integration sites are within tRNA open reading frames. The loss of a functional tRNA could potentially lead to a reduction in host fitness, so many phage have evolved such that integration will reconstitute a functional tRNA gene. This holds true for many other *attB* sites within important genes.

There are cases where prophage integration does not reconstitute a functional gene and leads to loss of protein function. For example, the integration of L54a and ϕ 13 phages into the *S. aureus* chromosome leads to a loss of a functional lipase and β -toxin, respectively.

Genomic Rearrangement

Bacteria harboring multiple prophages with similar DNA sequences can give rise to homologous recombination events to cause large genomic rearrangements. The location of rearrangements in the chromosome are often correlated with the loci of prophages. For example, from a sequence alignment, it was observed that the genomic differences between an American and Japanese

Table 1 Non-exhaustive list of phage-encoded virulence factors

Note: Table adapted and extended from Brüssow, H., Canchaya, C., Hardt, W., 2004. Phages and the evolution of bacterial pathogens: From genomic rearrangements to lysogenic conversion. *Microbiology and Molecular Biology Reviews* 68 (3), 560–602.

S. pyrogenes M3 isolate could be largely explained by two sequential inversions. One of these inversions occurred between the lysis modules of two prophages.

Genomic rearrangements may also aid phage evolution. In the example of *S. pyrogenes*, the lysogenic conversion genes were outside of the inversion region. The inversion event shuffled virulence genes between the prophages. This could lead to new prophages with altered host specificity and behaviors.

Conclusion

Lysogeny can change the phenotype, fitness and evolution of the bacterial host cell. In the case of bacterial pathogens, prophages allow the acquisition of new traits such as virulence factors which in turn may improve the host's fitness. This is emphasized by the observation that prophages have played a vital role in the emergence of several clinically relevant human pathogens, such as the food-borne pathogen *E. coli* O157:H7 and cholera causing *V. cholerae*. Prophages also drive bacterial evolution through the introduction of new genes, the disruption of existing genes and mediating large genomic rearrangements within the host.

In the laboratory, temperate bacteriophages have provided numerous tools and reagents for molecular biology, and have been used as models of regulatory networks and biological switches. The study of bacteriophages λ , P2 and its relatives, Mu, P1, N15 amongst others have provided many seminal contributions to these fields. This article has touched on several of these mechanisms and simultaneously highlighted the diversity in means for achieving the persistence of DNA, maintaining the prophage in a quiescent state and for exiting lysogeny. As the number of bacterial genomes sequenced continues to grow, new prophages using novel mechanisms to achieve these lysogenic functions will no doubt be discovered.

Glossary

Induction A process by which a temperate phage switches from the lysogenic state to the lytic pathway, typically in response to a perturbation such as damage to the host cell's DNA.

Lysogenic pathway One of the two possible pathways following temperate phage infection, characterized by suppression of viral replication and lytic functions. The bacterial cell carrying the dormant phage (e.g., in the form of a prophage) is termed a lysogen.

Lytic pathway The other possible pathway following temperate phage infection, in which phages replicate rapidly

and eventually kill (lyse) the host cell, releasing progeny viruses.

Multiplicity of infection (MOI) The number of viruses co-infecting the same cell.

Prophage A phage in the lysogenic state, which has integrated into the host genome. Replication of the viral DNA occurs passively during replication of the bacterial chromosome.

Temperate phage A bacteriophage that is capable of the dormant (lysogenic) pathway, in addition to the active (lytic) one.

Introduction

The defining lifestyle of most bacteriophages, analogous to the behavior of higher viruses, is one in which infection is followed by rampant viral replication and the release of numerous mature progeny, often accompanied by death of the host cell (lysis). However, a subset of phages, denoted as *temperate*, are capable of an alternative lifestyle called lysogeny, where the violent cataclysm is replaced by viral dormancy: Following infection, the phage genome is maintained inside the bacterial host – either integrated (as a *prophage*) into the bacterial chromosome, or replicating extra-chromosomally – with all virulent functions shut off. The dormant phage, now an integral part of the bacterial cell, is inherited from generation to generation. However, while dormant, the phage typically maintains the potential for lytic induction: a switch back to the virulent pathway in response to specific signals indicating stress to the host cells.

Multiple aspects of the lysogenic lifestyle are the subject of current studies. These include the physiological costs and benefits, to both phage and host, of viral dormancy, as well as the ecological, medical, and evolutionary consequences of lysogeny. Here we focus on a single element: The decision between lysis and lysogeny, made by temperate phages upon infection of the host. In particular, we will devote most of our attention to the decision by bacteriophage lambda, which infects *Escherichia coli* (Fig. 1). Through more than half a century of genetic, biochemical, and biophysical studies, lambda has become arguably the best-characterized biological system, albeit one that still presents many open questions. As we review the lambda lysis/lysogeny decision, we will also provide examples for some of the ways that other temperate phages make this choice. In light of the overwhelming diversity of phage lifestyles, it is certain that many more ways in which phages pursue their lysis/lysogeny decisions remain to be discovered.

Owing to the relative compactness and tractability of bacteriophages, many of their functions have been studied not only for their intrinsic value, but also as simplified models for the behavior of higher biological systems. This is also the case for the lysis/lysogeny decision, which serves as a paradigm for the way genetic circuits, receiving external inputs, make binary cell-fate choices. In that role, for example, the decision by phage lambda has provided insights about the transition in and out of dormancy by HIV, and, beyond viruses, regarding the process of cellular differentiation during metazoan development. At the heart of lambda's ability to inform us on higher organisms are common features of binary decision circuits across biological systems, notably, the utilization of auto-regulating, fate-determining genes to provide high cell-state stability while simultaneously allowing efficient fate switching in response to external signals.

As part of its paradigmatic role, lambda has also served as a testbed for the idea of creating a quantitative description, formulated in mathematical terms, for the function of the genetic circuit, with the goal of predicting the decision outcome for given initial conditions. While efforts in this direction have yielded significant progress, they have also been limited by the phenomenon of cellular individuality, whereby genetically identical cells, in a uniform environment, nevertheless end up pursuing different paths. To explain the indeterminacy of single-cell choice, researchers invoked the effect of stochastic biochemical fluctuations ("noise") on the decision circuit. With this concept, too, lambda has paved the way for the elucidation of cellular stochasticity and its consequences across the fields of microbiology, development, ecology and medicine.

Fig. 1 The post-infection decision of bacteriophage lambda. Following infection of an *E. coli* cell, a binary choice is made between lysis, defined by rampant viral replication and cell death, and lysogeny, in which the viral DNA is integrated into the host's genome to become a dormant prophage. The lysogenic state is stably maintained, but a switch back to lysis can be induced by cellular damage. Adapted with permission from Golding, I., 2016. The Post-Infection Decision of Phage Lambda

A decision between lysis and lysogeny first takes place following lambda infection, upon entry of the viral genome into the *E. coli* cell (Fig. 1). A genetic circuit encoded by the phage, integrating inputs from the host (and, indirectly, from the extracellular environment), converges on one of the two developmental pathways. If lysis is chosen, the decision is irreversible and, hence, the role of the decision circuit is complete. If, however, the choice is lysogeny, that fate needs to be actively maintained over the long term, using a small subset of the decision gene network. In addition to repressing all virulent functions, this maintenance circuit (known as a genetic “switch”) perpetuates a continuous version of the lysis/lysogeny decision: at any given time, whether to maintain stable dormancy or, if cellular conditions change, undergo lytic induction, switching back to the lytic pathway by relieving the repression of virulent functions.

The choice between lysis and lysogeny can be seen as one of timescale, namely, whether to reproduce (and kill the host) immediately, or at a later, yet to be determined, time. An optimal choice, one which maximizes – in the long term – the expected number of progeny, requires knowledge of the state of the infected cell, e.g., how likely it is to support successful viral reproduction, as well as its environment, e.g., what the chances are that newly-released phages will find additional targets to infect. Below we discuss how lambda and a few other phages measure these critical parameters. From a theoretical point of view, the optimization problem that underlies decision making by temperate phages continues to be an area of considerable interest.

The genetic circuit governing the lambda decision is depicted in Fig. 2. The decision involves a dense network of regulatory interactions between phage genes, as well as multiple inputs from various host functions. The regulatory interactions involve diverse molecular mechanisms, modulating all stages of gene expression: transcription initiation (through transcription factors, alternative promoters, and interference between neighboring promoters) and elongation (anti-terminators), post-transcription (antisense RNA), translation, and post-translation (protein lifetime). The role of some of these interactions in the decision process has been elucidated through genetics, biochemistry, and mathematical modeling of the circuit. The utility of other interactions, however, is less clear. It is possible that those come into play under infection conditions that are not emulated by standard laboratory conditions, serving to increase the robustness of the decision to environmental and biochemical fluctuations.

To gain insight into the decision process, it is helpful to follow the cascade of transcriptional events taking place on the lambda genome following infection, and how these events diverge en route to each of the two possible outcomes (Fig. 3). Upon entry of the viral genome into the *E. coli* cell, transcription begins from the left (P_L) and right (P_R) early promoters. Transcription is initially attenuated at the t_{L1} and t_{R1} terminators, such that only a single protein is expressed from each promoter: N from P_L and Cro from P_R . One of these proteins, N, is an anti-terminator that allows readthrough at t_{L1} and t_{R1} , as well as at another terminator, t_{R2} , further downstream of P_R . This leads to the expression of additional lambda genes. These “delayed early” genes include those that allow progression of the lytic pathway: O and P, required for phage genome replication, and Q, which controls the expression of multiple lytic genes. However, CII and CIII, whose products drive the establishment of lysogeny, are also produced from those same left and right transcripts.

If the Q protein accumulates to a sufficient level, it abrogates termination at the t_R site, to enable expression from the late lytic promoter P_R of genes responsible for the production of new viral particles and lysis of the host cell, and thus completion of the lytic cycle. For the alternative route of lysogeny to be taken, Q production needs to be reduced. This is achieved by CII, which activates the P_{aQ} promoter to produce an antisense transcript to Q, resulting in inhibition of Q expression and thus preventing the expression of the late lytic genes. In addition, CII promotes the lysogenic pathway by activating the P_1 promoter, whose product Int

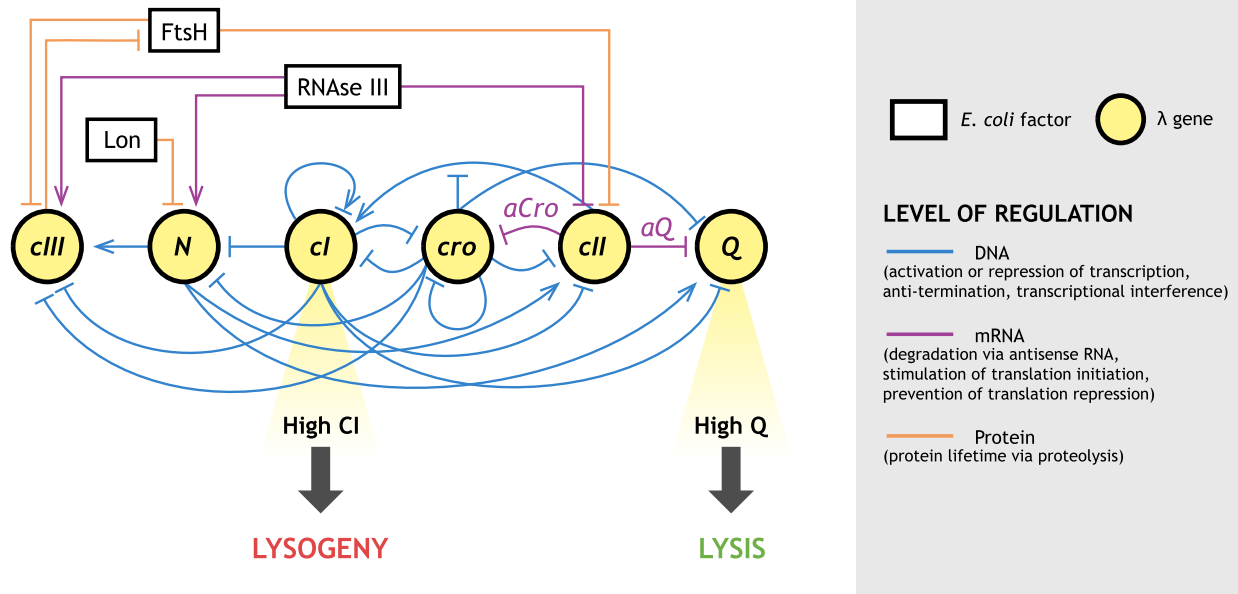

Fig. 2 Key lambda genes and host factors involved in the lysis/lysogeny decision. Regulatory interactions between the various nodes rely on diverse molecular mechanisms, at the level of phage DNA, mRNA and proteins.

catalyzes integration of the phage genome into the bacterial chromosome. Finally, CII activates the repression establishment promoter P_{RE} to produce CI. CI shuts off transcription from P_L and P_R and regulates its own transcription, now from the repression maintenance promoter, P_{RM} . In the lysogenic state, P_{RM} expression of CI is the only transcriptional activity from the decision network of the dormant prophage.

What makes the post-infection decision elusive, even after decades of meticulous interrogation, is that, qualitatively, the expression patterns of early genes are similar in lytic and lysogenic cells, and therefore appear unpredictable of the eventual outcome. Consider *cII*, the key driver of lysogenic choice. Its expression from P_R takes place in a limited time window of ~ 15 min, regardless of the eventual choice. Whether this transient expression will result in lysogeny depends on the exact timing and on the maximal CII level obtained. CII kinetics are regulated at multiple levels – at the promoter (P_R) and terminator (t_{R1}), as well as the mRNA and protein lifetimes. This multi-layer regulation provides the means by which the lysis/lysogeny decision is modulated by host and phage parameters, as discussed later.

Whereas the decision by lambda is by far the one best characterized, progress has also been made towards understanding the decision circuits of other phages. In multiple cases, the decision network is quite reminiscent of lambda's, with the *cl-cII-cIII* module conserved, and an orchestrated gene expression cascade taking place. Even in phages that are otherwise very different from lambda, a dual repressor motif similar to the *cl/cro* pair (discussed in more detail below) is often present, and an auto-regulatory viral “repressor”, which both establishes and maintains the lysogenic state, appears to be near universal. Among temperate phages whose decision process has been studied in some detail, a few offer slight variations on lambda, for example, P22, a “lambdoid” phage (i.e., one with a similar genome architecture to lambda), where the Cro-analog (*ant*) directly inactivates the CI-analog (*c2*) by binding to it and preventing it from effectively binding to DNA. Others exhibit dramatically different behavior. P4, for example, is a “satellite phage”, a genetic element that requires other viruses for its own propagation. Rather than having a global repressor, which establishes and maintains lysogeny by regulation of transcription initiation, the outcome and maintenance of the decision in P4 are driven by control of transcription termination, mediated by RNA-RNA interactions. The default pathway in P4 appears to be lysogeny, with the alternative state, in the absence of a co-infection by a helper phage, being that of a multi-copy plasmid. In that state, infection by a helper phage induces the transition into lysis.

Counting by Infecting Phages

The perceived role of the decision circuit, as stated above, is to choose between lysis and lysogeny based on the conditions of infection. A key question is, thus, how these conditions are sensed by the infecting phage and processed by the decision circuit to yield an optimal outcome. This question is far from settled. To begin with, which aspects of the infection event are pertinent to the outcome? The parameter best characterized in terms of its effect on the lambda lysis/lysogeny choice is the multiplicity of infection (MOI), namely, the number of phages co-infecting the cell. It was found long ago that, the higher the MOI, the higher the probability of lysogeny. Fig. 4 depicts the results of an experiment measuring the relation between the two observables. A known number of bacteria is mixed with varying concentrations of phages, and, once infection is allowed to proceed, the number of

Fig. 3 The cascade of transcriptional events during the lambda lysis/lysogeny decision. Regulatory elements and their interactions are depicted on the relevant region of the lambda genome. The expression pattern of early genes is qualitatively similar irrespective of the eventual fate. After a decision has been reached, different sets of genes are expressed to execute the lysis/lysogeny choice.

resulting lysogens is measured using selection for an antibiotic marker that was engineered into the viral genome. To interpret the experimental results, the measured values are compared to a simple mathematical model, in which random phage-bacteria encounters (following mass-action probability and Poisson statistics) result in lysogeny if the number of phages co-infecting a single cell reaches some number m^* . As seen in Fig. 4, the measured data is consistent with a value of $m^* = 2$, i.e., a scenario where infection by a single phage leads to lysis, whereas simultaneous infection by two or more phages results in lysogeny.

The notion that infecting phages are able to count their numbers in the cell, and then decide on the mode of action based on that number, is intriguing both mechanistically – how do viruses count? – and in terms of its utility – why do they do so? In terms of mechanism, it is commonly held that counting is mediated through the level of CII reached during infection. The MOI affects both CII production (through increased gene dosage) and degradation (through production of CIII, which protects CII from degradation by FtsH, see below). As described earlier, high CII level triggers lysogeny by driving the expression of the integrase and CI, and inhibiting late-lytic gene expression from $P_{R'}$. However, an alternative hypothesis, motivated by recent single-cell experiments and mathematical modeling, posits that phage counting simply reflects the number of cI gene copies, whereas CII levels respond only weakly to MOI, possibly due to the auto-repression of P_R by Cro. If enough CI accumulates, it will then activate its own transcription from P_{RM} and shut down expression of the lytic genes. Elucidating phage counting is complicated

Fig. 4 The dependence of lysogenization on the multiplicity of infection: bulk data. A known number of *E. coli* bacteria is infected with varying concentrations of lambda phage, and the number of resulting lysogens is measured using selection for an antibiotic marker that was engineered into the viral genome. The experimental trend is reproduced by a simple mathematical model, where infection by a single phage leads to lysis, whereas simultaneous infection by two or more phages results in lysogeny.

considerably by the fact that the lambda genome begins replicating shortly after infection, i.e., during, not after, the lysis/lysogeny decision. That early replication plays a role in the decision is evidenced by the fact that replication-deficient lambda mutants require a higher number of initial viruses to achieve lysogeny, compared to wild type phages.

As for the biological utility of choosing lysogeny at higher MOI, the common interpretation is that the number of co-infecting phages is used by lambda as a proxy for the ratio of phage-to-bacteria abundance in the surrounding environment. That ratio, in turn, serves to assess the chances of successful infection by the next generation of phages, should the lytic pathway be chosen. Specifically, high MOI indicates that phages outnumber bacteria and that, therefore, releasing more phages into the environment is futile, since they are unlikely to find new bacterial targets. Hence, high MOI advocates lysogeny. Conversely, low MOI indicates the availability in the environment of yet-uninfected bacteria, thus promoting the release of more viral particles through lysis.

Consistent with the idea that lambda measures the multiplicity of infection in order to assess the abundance of uninfected bacteria in the environment, recent studies found additional ways by which phages can infer this kind of information. During initial rounds of infection of *Bacillus subtilis*, phage phi3T expresses the genes *aimR* and *aimP*. AimR binds to the phage DNA and activates the transcription of *aimX*, which blocks the lysogenic pathway in a mechanism not yet elucidated. The lytic pathway is thus favored in the initial infections. Meanwhile, AimP, a short peptide, is secreted into the extracellular medium, where it accumulates and is taken up by uninfected cells. When some of these cells are later infected, the intracellular AimP, now at high concentration, binds to and inactivates AimR, resulting in repression of *aimX* expression. Consequently, lysogeny is favored in later rounds of infection. Using this intercellular communication system (termed “arbitrium”), infecting phi3T phages are able to record past infections of other cells and tune their lysis/lysogeny decision based on this knowledge.

The ability to hijack the host’s quorum sensing system is also found in VP882, a temperate phage that infects *Vibrio cholerae* and other *Vibrio* species. The outcome of infection by VP882 depends on a repressor (Gp59) that inhibits the expression of the lytic regulator (Gp62), thus promoting the lysogenic pathway. During infection of *Vibrio cholerae*, the phage also expresses VqmA_{phage}, a homolog of the host’s endogenous quorum sensing receptor, VqmA. When bound by *Vibrio*’s autoinducer, DPO, VqmA_{phage} promotes the expression of an antirepressor (Qtip), which sequesters the repressor Gp59, allowing genes involved in the lytic pathways to be expressed. Consequently, when the bacterial density is high, the increased DPO level in the medium promotes the lytic pathway of infecting VP882. Note that, in contrast to phi3T above, which relies on a phage-specific secreted molecule, here, VP882 assesses the bacterial density via an autoinducer encoded by the host.

The cases described above, in lambda and other phages, as well as the ecological argument mentioned, all support the idea that increased phage-to-bacteria ratio promotes lysogeny. However, whether this rule applies universally is still unclear. The propensity for lysogenization by bacteriophage P1, for example, is reported to be insensitive to the number of viruses infecting the host cell. In infections by phage Mu, the probability of lysogeny appears to decrease with the multiplicity of infection, although this trend may reflect the virus’ toxicity to the host at high MOI.

There is also an ongoing debate whether, outside the artificial lab environment, bacterial density is correlated – positively or negatively – with the occurrence of lysogeny, and how to interpret the observed trends. Ecological studies of lytic infections support a “kill the winner” model, in which viral infection increases host diversity by preventing overabundance. However, the dynamics of temperate viruses are much harder to interpret, and the relationship between host density and outcome frequencies is unclear. Previous studies of prophage induction found that lysogeny is more prevalent at low host density, consistent with the picture above of increased lysogenization at high MOI. A more recent work, using metagenomics analysis, reported an inverse trend, but the interpretation of these newer findings is a subject of some controversy.

Whereas the multiplicity of infection is the best-characterized driver of the lambda lysis/lysogeny decision, it is definitely not the only one. Recall that multiple host factors interact with the decision circuit (Fig. 2 above). One such factor is FtsH, a membrane-bound ATP-dependent protease. During lambda infection, FtsH degrades CII and thus impacts the choice between lysis and lysogeny. Part of FtsH’s influence comes about through the MOI, specifically, the dosage-dependent production of CIII, which

is believed to protect CII by serving itself as a target for FtsH. However, beyond the response to MOI, the level and activity of FtsH are regulated by the physiological state of the cell, thus providing a means for the condition of the host cell to inform the lysis/lysogeny decision. For example, the increase in lysogenization at low temperature can be attributed to a decrease in FtsH levels, as well as an increase in the thermodynamic stability of CII, to which FtsH is highly sensitive. Temperature also impacts the decision circuit through its effect on another bacterial protease, Lon, which is expressed in a temperature-dependent manner and targets the N anti-terminator. Two other cellular sensors, cyclic adenosine monophosphate (cAMP) and guanosine tetraphosphate (ppGpp), have also been reported to affect the lysis/lysogeny decision, possibly by inhibiting FtsH. Cellular state also influences the lambda decision through RNase III, whose levels are modulated by the *E. coli* growth rate. RNase III promotes degradation of *cII* transcripts, stimulates ribosome binding and translation initiation of *cIII*, and blocks auto-repression of *N* translation during early infection, thus affecting multiple nodes of the decision network. The ways in which the decision circuit assesses the state of the cell via these and other physiological sensors remain a promising direction for future interrogation.

The View From the Single Cell

Most of what we know about lambda's post-infection decision comes from studies that used traditional genetic and biochemical assays, performed in bulk cultures, and thus involving the averaging of all measured observables over millions of cells. But these individual cells may, in fact, exhibit very different phenotypes. Over the last decade, traditional bulk assays have begun to be supplemented by microscopy-based studies, in which the infection process is followed in real time, at the level of individual cells and phages. Fig. 5(A) shows an example of such an experiment. Here, the lambda capsid was labeled using multiple copies of a fluorescent protein, such that each phage particle appears under the microscope as a diffraction-limited spot. The infected cells were simultaneously imaged using phase contrast microscopy. Time-lapse images show the infection and its outcome for two individual cells. The first cell, infected by a single phage, proceeds to produce more viral proteins (green) and lyse within two hours. The second cell, co-infected by three phages, survives to grow and divide. That cell has chosen the lysogenic pathway, as indicated by the production of a red fluorescent protein, here expressed from the lysogeny establishment promoter, P_{RE} .

Following many infection events in this manner allows one to determine how the decision outcome – lysis or lysogeny – depends on the infection parameters, such as the MOI. Fig. 5(B) shows that the fraction of cells choosing lysogeny increases with MOI, a trend consistent with the observations in bulk. However, in contrast to our original interpretation of the bulk data (Fig. 4 above), the single-cell data suggests that the MOI dependence is probabilistic rather than deterministic: At MOI of 2, for example, an infected cell has about a 50% chance of going either lytic or lysogenic. In other words, when we observe a cell co-infected by two lambda phages, we have no way of telling what route will be chosen!

We are thus confronted with the indeterminacy of single-cell behavior: genetically identical cells, all subject to the same environment, exhibiting different phenotypes from each other. This phenomenon is observed throughout biology, and its origins are a subject of intensive interrogation. According to the prevailing picture, cellular individuality reflects the inherent randomness of biochemical reactions in the cell. In this view, the unavoidable fluctuations in molecular copy number and in the timing of events render the lambda decision “noisy” and unpredictable, rather than precise and deterministic. The plausibility of this argument was first demonstrated using a computational simulation of the lambda decision circuit, showing that fluctuations in biochemical reactions can result in diverging cell fates among infected cells. The concept of noise-driven decisions then evolved and was used to explain cell-fate indeterminacy in higher systems, including the transition in and out of HIV latency, as well as the differentiation and reprogramming of metazoan cells.

Fig. 5 The lysis/lysogeny decision at the single-cell level. (A) Images from a live-cell movie following the fate of two *E. coli* cells, infected by fluorescently-labeled lambda phages. The upper cell, infected by a single phage, proceeds to produce new viral particles and undergo lysis. The lower cell, co-infected by three phages, enters lysogeny, as indicated by a fluorescent reporter for P_{RE} activity, and proceeds to divide normally. (B) The fraction of cells undergoing lysogeny as a function of the multiplicity of infection, as measured from >1000 infection events. In contrast to the original modeling of the bulk data (Fig. 4 above), the single-cell curve rises gradually, suggesting that the MOI dependence is probabilistic rather than deterministic. (C) Incorporating the effect of intracellular viral concentration (MOI divided by cell volume) captures the experimental data and yields a decision curve that is markedly more step-like. Adapted from Zeng, L., Skinner, S.O., Zong, C., *et al.*, 2010. Decision making at a subcellular level determines the outcome of bacteriophage infection. Cell 141 (4), 682–691, Copyright 2010, with permission from Elsevier.

Fig. 6 Detecting the transcriptional activity of individual lambda phages. (A) Each phage is detected through the binding of fluorescently-tagged ParB proteins to the *parS* sequence, engineered into the lambda genome. mRNA molecules transcribed by the phage are simultaneously detected using single-molecule fluorescence *in situ* hybridization (smFISH). (B) Four lambda genomes (cyan) inside a single infected cell, at 10 min after infection. Individual phages vary in their transcriptional activity, with one transcribing *cro* (green) and two others producing *cl* (red).

But the fact that we can describe cell fate decisions probabilistically does not necessarily mean that we should settle for such a narrative and give up seeking a deterministic description of the decision process. While biochemical stochasticity is undisputedly present, automatically attributing all cellular indeterminacy to unknowable “noise” may be taking the easy path. One must consider the alternative hypothesis, which is, that our inability to predict the decision outcome reflects a failure to account for additional cellular variables that have a deterministic effect on the decision. So long as these “hidden variables” remain unknown to us, the decision will appear more random than it truly is, and our understanding of it remain limited.

And, in fact, a number of lambda studies suggest that incorporating additional variables can reveal a more precise decision at the single-cell level. It was first found that, for a given MOI, smaller cells are more likely to be lysogenized than larger ones. This should not surprise us, since decreasing the size of the infected cell is, to a first approximation, the same as infecting with a larger number of phages: both result in an increased concentration of viral gene products in the cell. Detailed analysis revealed that a unique arithmetic combination of the MOI and cell size yields a more step-like (and therefore, more deterministic) probability of lysogenization (Fig. 5(C)). The way in which the infection parameters combine to yield a sharp decision curve points to a nonlinear interaction between the co-infecting phages as they converge on the cell’s fate. Elucidating the nature of this interaction will require characterizing the spatiotemporal dynamics and genetic activity of individual phages within the infected cell. Fluorescent reporters for phage capsid, genome, RNA and protein products, needed for such an investigation, are now becoming available (Fig. 6).

The Decision to Remain Dormant

If, following infection, the lysogenic route is chosen, control of cell fate is then handed over from the post-infection decision circuit to a smaller circuit, whose role is to maintain dormancy by repressing all virulent functions. The maintenance circuit must also be able to trigger a switch back to lysis (induction) when cellular conditions change. Thus, the dormant virus continuously re-evaluates its lysis/lysogeny decision. Some elements of lysogenic maintenance in lambda and other phages are covered by a separate article in this encyclopedia (Shearwin). Here we focus on the decision-making aspect of the maintenance circuit.

In lambda, lysogenic maintenance is handled by a subset of the post-infection decision network discussed above. The smaller maintenance circuit, known as the lambda “switch”, consists of two phage genes, *cl* and *cro*, transcribed respectively from two diverging promoters, P_{RM} and P_R (Fig. 7). The two gene products, CI and Cro, compete for binding to six operator sites (O_{R1-3} and O_{L1-3}) that regulate P_{RM} and P_R transcription, resulting in mutual repression by the two proteins. In the prophage state, high cellular level of CI represses transcription from P_R and P_L , thus maintaining viral dormancy. The lysogenic state is further stabilized by the formation of a DNA loop between O_{R1-3} and O_{L1-3} , secured by oligomerization of CI dimers bound at the two loci. Perturbations that reduce the level of CI (such as activation of the bacterial SOS response, discussed below), can lead to lytic induction. In this process, the inhibition of P_R and P_L is relieved, leading to transcription of early lytic genes, including *cro*. Cro then represses P_{RM} , leading to further reduction of CI level and allowing the lytic cascade to proceed. Despite decades of meticulous studies, recent experiments continue to reveal new features of the lambda maintenance circuit, such as the role of mechanical coupling between transcription, DNA supercoiling, and looping, and how this coupling may affect the stability of the lysogenic state.

As in the case of infection, the phage (now, prophage)-encoded circuit requires input from the bacterial host in order to sense the state of the infected (now, lysogenized) cell and use that information to choose optimally between lysis and lysogeny. Specifically, during lysogenic maintenance, the role of host input is to alert the prophage when the bacterial cell is in danger, indicating that it is time to escape the host through the lytic pathway. Lambda receives this information via *E. coli*’s SOS system,

Fig. 7 The maintenance of lambda lysogeny. (A) The lysogenic state is maintained by a regulatory circuit consisting of CI and Cro, expressed from the P_{RM} and P_R promoters, respectively. CI and Cro compete for binding at six operator sites (O_{R1-3} and O_{L1-3}), to determine which promoters (P_{RM} , or P_R and P_L) are active, and thus decide whether lysogeny is maintained or, instead, lytic genes induction takes place. Two examples of binding configurations are shown. On the left, CI dimers bind to four operator sites, resulting in DNA looping that ensures repression of P_R and P_L during lysogeny. On the right, binding of Cro to O_{R3} represses transcription of CI from P_{RM} and allows lytic genes to be expressed. (B) The regulatory interactions between CI and Cro form a bistable switch. The system can alter its state in response to a large perturbation, such as depletion of CI by RecA, leading to lytic induction, but is immune to small perturbations. Adapted with permission from Golding, I., 2016. Single-cell studies of phage λ : Hidden treasures under Occam's rug. Annual Review of Virology 3 (1), 453–472, permission conveyed through Copyright Clearance Center, Inc.

which, in response to cellular DNA damage, halts progression of the cell cycle and triggers DNA repair and mutagenesis. Under normal growth, expression of the SOS response genes is repressed by LexA. However, in the presence of DNA damage (due to, e.g., UV radiation), regions of single-stranded DNA accumulate, leading to recruitment and activation of RecA. Activated RecA facilitates LexA self-cleavage, de-repressing SOS genes, including RecA itself. Phage lambda is coupled to the SOS response through the self-cleavage of CI by activated RecA. The consequent drop in cellular CI concentration leads to the relief of *cro* repression, activation of the lytic pathway, and prophage induction. Many other temperate bacteriophages are also induced following treatment with UV radiation or DNA-damaging agents. However, some, like P2, appear to be non-inducible, and immune to the bacterial SOS system.

The *ci/cro* pair serves as a canonical example for a so-called “toggle switch”, a genetic module exhibiting two stable states, here corresponding to lysogeny and to the onset of lysis. Despite consisting of only two genes, the lysogeny maintenance circuit of lambda captures key features of cell-fate choice, as observed across the spectrum of biological complexity. Through the use of feedback (P_{RM} autoregulation by CI), the system achieves extremely high stability in the absence of external perturbations, with fewer than one spontaneous switching event per 10^6 cell doublings. At the same time, almost 100% of lysogenic cells switch to lysis in response to an inducing signal. These properties have made the lambda maintenance circuit an attractive starting point for understanding cellular differentiation and reprogramming in metazoans. In particular, lambda has served as a fertile test ground for the attempt to formulate a detailed biophysical description of cellular behavior, in the form of a mathematical model that uses the known molecular interactions to predict the resultant cellular phenotype. This effort has been, at least partly, successful. For example, a thermodynamic model can be written, describing the different binding configurations of CI at the operator sites that control transcription from P_{RM} , and this model used to predict the regulatory curve relating CI concentration in the cell to P_{RM} activity. The theoretically predicted curve shows good agreement with experimental measurements of this regulatory relation (Fig. 8). The theoretical calculations can

Fig. 8 A theoretical biophysical model captures P_{RM} regulation by CI. The regulatory curve relating CI concentration in the cell to P_{RM} activity can be predicted from a thermodynamic description of the possible binding configurations of CI at the O_{R1-3} and O_{L1-3} operator sites. The theoretically predicted curve agrees with the experimental measurement of the regulatory relation. The average amount of CI protein present in each lysogenic cell can be estimated by requiring that CI production is exactly balanced by CI elimination (via dilution, due to cell growth and division). Adapted from Sepúlveda, L.A., Xu, H., Zhang, J., Wang, M., Golding, I., 2016. Measurement of gene regulation in individual cells reveals rapid switching between promoter states. *Science* 351, 1218–1222, reprinted with permission from AAAS; and from Golding, I., 2011. next be utilized to estimate the amount of CI protein present in a lysogenic cell, by requiring that CI production is exactly balanced by CI elimination (via dilution, due to cell growth and division) (Fig. 8).

The eventual test for a theory of the lambda switch is to successfully predict the key phenotype, namely, whether a given cell will remain in the lysogenic state or, instead, switch to lysis. In attempting to answer this question, we are again confronted with the challenge of cellular individuality: In the absence of an external signal, only one out of a million lysogens in a growing culture will spontaneously switch. Can we predict which cell this will be? It is widely believed that the answer is negative, and that we may only aspire to predict the probability of induction, not the actual fate of an individual cell. This is because spontaneous induction is considered a stochastic process, driven by random fluctuations of CI levels in the cell. Small drops in CI number will be corrected by the negative feedback in the P_{RM} -CI circuit, raising CI level and thus reverting to the mean. However, rare, larger drops will overcome the feedback and lead to de-repression of P_R , Cro production and onset of the lytic pathway. In this picture, spontaneous lytic induction is analogous to the way random thermal motion drives a physical system to transition from one stable state to another (Fig. 7 above). The challenge of theoretically predicting the behavior of the *ci/cro* switch dwarfs in comparison to the larger goal of predicting cell fate following infection, when the full decision network (Fig. 2 above) comes into play.

Conclusion

The prevailing narrative for the lambda lysis/lysogeny decision, both following infection and during lysogenic maintenance, offers only a probabilistic prediction, rather a deterministic one, as to which path an individual cell will choose. This probabilistic point of view is similarly applied, further afield, to the choice of latency by mammalian viruses and to cellular differentiation and reprogramming. These decisions are all held to be indeterminate, noise-driven processes. Bacteriophage lambda, where this picture originally emerged, also bears the potential to challenge the probabilistic view by revealing previously-hidden variables that bias the decision outcome, or even determine it in full. Future studies, describing the lysis/lysogeny decision in individual phages and cells, in real time, will be key to delineating true randomness from the hidden precision of cellular decision-making.

Glossary

Accessory gene A gene that is not required for the lifecycle of the mobile genetic element, but often confers a fitness advantage to the bacterial host, for example, by encoding genes involved in virulence.

Burst assay Quantification of the number of bacteriophage progeny produced by one infected host cell.

Capsid Protein shell in which the phage genome is packaged.

Helper phage A phage that induces transfer of a satellite phage.

Lytic (virulent) phage A phage that takes over the host to produce progeny phage culminating in lysis of the host cell, and is unable to integrate into the host chromosome or otherwise lysogenize the bacterial host.

Mobile genetic element (MGE) DNA capable of moving within or between genomes.

Phage inducible chromosomal island (PICI) A genetic element that is induced to excise, replicate autonomously and package itself into helper phage structural components.

Phage-inducible chromosomal island-like elements (PLEs)

Anti-phage islands found in clinical isolates of *Vibrio cholerae*, specifically induced by, and inhibitory toward, the lytic phage ICP1.

Satellite phage Subviral element lacking genes encoding functions needed to complete the phage lifecycle. Thus for their multiplication, satellites parasitize a helper phage during co-infection of a host cell.

Staphylococcus aureus pathogenicity island (SaPIs)

Prototypical PICI elements that are ubiquitous in *S. aureus* and carry virulence genes.

Temperate phage (prophage) A phage that can undergo either a lytic cycle or integrate into the host genome to be transmitted vertically until induced by environmental cues to re-enter the lytic cycle.

Transduction Packaging and transmission of bacterial DNA inside phage virions to new host cells.

Introduction

Phages profoundly impact the evolutionary landscape of their bacterial hosts, both through predation, which selects for hosts with defenses to overcome phage killing, and through mobilization and dissemination of genetic material. Phages are the most abundant biological entities on the planet, making phage-mediated genetic transfer a critically important mechanism of gene mobilization between bacteria. Phages with strictly lytic lifecycles infect susceptible bacterial cells and redirect cellular metabolism to promote phage replication, resulting in the release of infectious phage progeny through cell lysis. In contrast to lytic phages, temperate phages are able to integrate into their host genome where they can be transmitted vertically. It is well-established that integrated phages can dramatically alter bacterial phenotypes by providing their host with novel genes. One of the most clinically relevant examples is the CTX prophage integrated into the genome of epidemic *Vibrio cholerae*; CTX encodes cholera toxin, the virulence factor responsible for the profuse watery diarrhea that is the hallmark of the disease cholera. For many temperate phages, signals that trigger the prophage to re-enter into the lytic cycle culminate in the lysis of the host cell and the release of progeny phage. Both lytic and temperate phages can occasionally mis-package regions of the host genome and move it to new recipient cells in a process called generalized transduction. Additionally, temperate phage can excise along with adjacent areas in the host genome, and move these regions at a higher frequency in a process called specialized transduction.

In sharp contrast to these forms of “passive” transduction, there are mobile genetic elements, the phage satellites, that have evolved to precisely exploit phages for high-frequency transfer. These subcellular elements are consequential for bacterial and phage evolution as both providers of novel genetic content and as parasites of phages. Their impact can often go overlooked or be misinterpreted, as observing the transfer of a satellite phage requires a biological relevant tripartite system: the satellite phage, a compatible helper phage and a susceptible bacterium. It was initially thought that the genetic element encoding the toxic shock syndrome toxin was contained on a prophage in *Staphylococcus aureus*, though in the late 1990s it was discovered that this toxin containing island was able to excise, replicate and package itself not as an independent temperate phage, but rather through parasitizing a temperate phage for mobilization. This was demonstrated to be an autonomously replicating pathogenicity island, and was designated SaPI1, for “*Staphylococcus aureus* pathogenicity island 1”. Since this discovery, much has been learned about the SaPI lifecycle, including how SaPIs are induced by specific phages, how they replicate and efficiently package their genomes into virions leading to the spread of virulence genes across large phylogenetic distances. Most *S. aureus* virulence factors are found on these phage satellites, highlighting the phage-dependent lifestyle as a successful means to efficiently spread genetic material. Importantly, SaPIs are the archetype of a larger group of MGEs known as phage-inducible chromosomal islands (PICIs) which have only recently been found to be widespread among Gram-positive bacteria, and prevalent among Gram-negative Gamma-proteobacteria. PICIs have several features in common, which will be discussed below. Other newly discovered PICI-like elements

Fig. 1 Genetic organization of representative phage-inducible chromosomal islands. Representative genomes of Gram-positive (SaPI1 and EfCIV583) PICIs and *V. cholerae*'s PLEs (PLE1). All of these satellites share several features, including gene(s) involved in integration and excision from the bacterial chromosome (Int and Xis as well as the left and right attachment sites) in yellow, genes involved in regulation of gene expression in blue (although genes involved in PLE gene regulation have not yet been identified), a replication module consisting of an origin of replication (Ori) and replication genes in purple required for PICI replication, as well as genes involved in packaging and interference with their helper phage in grey. SaPIs additionally encode several genes involved in virulence, including production of toxic shock syndrome toxin (*tsf*), enterotoxins K and Q (*entK* and *entQ*), and *ear* conferring ampicillin resistance. In black are genes encoding hypothetical proteins.

(PLEs) do not share obvious homology to known PICIs, yet are also induced by specific phages, suggesting that the known repertoire of genomic islands mobilized by phages only represent the tip of the iceberg when it comes to phage-mediated genome flux.

Where there is experimental evidence, we will compare genetic elements that are mobilized by phages, highlighting what seem to be generalizable and convergent strategies that these elements use to effectively co-opt their inducing phage, as well as what is unique about these different islands. As we will see, the ability of phages to specifically mobilize regions of their host's chromosome involved in pathogenesis and phage resistance cautions against the use of phage in treating certain bacterial infections, as such mobility has the potential to stimulate evolutionary innovation and undermine the apparent benefits of harnessing phage as antibacterial agents.

Genetic Organization

PICIs and PLEs share many conserved features, which underscores several key elements of their lifecycle as phage satellites and also allows for identification of novel PICIs through sequence analysis. All PICI genomes are characterized by (1) specific attachment sites in their hosts genome, (2) a lack of phage structural or lytic genes and (3) a size of around 15 kb. PICIs have analogous genetic organization to phages, with genes clustered according to function. SaPIs have genes arranged in four modules: regulation, integration and excision, autonomous replication, and packaging (Fig. 1). Functionally, all PICIs discovered thus far also have strategies to interfere with helper phage propagation. In addition to the modules that allow for the propagation of PICIs, many contain accessory genes that result in the phenotypic conversion of a host carrying these mobile genetic elements to a more virulent state. PLEs appear to also have their genes arranged in operons, though PLE-encoded ORFs are not homologous to known PICI genes and few PLE-encoded gene products have known functions. Like the PICIs, PLEs lack obvious phage structural or lytic genes and they have unique attachment sites, though with genomes ranging from 18 to 19 kb, PLEs are larger than the archetypal SaPIs, and, as of now, have not been shown to be capable of autonomous replication in the absence of their inducing phage. Below we will discuss how PICIs and PLEs progress through their lifecycle starting with integration and induction.

Integration and Excision, Gene Induction, and Replication

Both PICIs and PLEs are integrated in a site-specific manner in their bacterial host genome. When integration occurs, the attachment site in the PICI, known as the *attP* site (*attS* for SaPIs), recombines with the bacterial chromosomal attachment site, *attC*, resulting in the creation of unique left and right attachment sites when integrated (*attL* and *attR*, respectively). An integrase (Int), a hallmark of MGEs such as satellite phage, drives the recombination between the bacterial chromosome and the incoming island. For SaPIs, Int is a tyrosine integrase and for PLEs, Int is a large serine recombinase. In both systems, integration of the

Fig. 2 The lifecycle of SaPI and PLE showing induction, replication and packaging. A schematic of the steps of a PICI lifecycle, contrasting an archetypal SaPI on the top and PLE on the bottom. SaPIs and PLEs are induced by specific helper phage, yet only SaPIs are induced by a temperate phage, which can be activated by the SOS response. SaPIs and PLEs replicate upon induction by their helper phage to several copies to nearly 1000 copies in the case of PLEs. Both PLEs and SaPIs transmit horizontally, but since it is unknown how PLE transduces, only the SaPI packaging is shown. SaPIs encode several mechanisms which interfere with helper phage, ensuring specific packaging and horizontal transmission of only the SaPI genome.

satellite phage is catalyzed by *Int* recognition of the *attC* site, and additional proteins are not required for acquisition. SaPIs integrate into one of six primary *attC* sites, while two *attC* sites are known for PLEs: PLEs 1, 3, 4 and 5 integrate into the *V. cholerae* repeat (VCR) while PLE 2 integrates into the hypothetical gene VCA581. The use of the VCRs as an attachment site for most PLEs provides immense flexibility for PLE integration, as VCRs are present in > 100 copies in *V. cholerae*.

Int is also required for excision of the satellite phage from the chromosome, but it is not sufficient. SaPIs encode an excisionase, *Xis*, which is required for excision and is only expressed upon helper phage mediated de-repression of SaPI genes. PLEs also require the presence of their inducing phage to excise, though the reason for this dependence differs. In contrast to SaPIs, which encode their own excisionase, PLEs utilize a phage-encoded recombination directionality factor to trigger excision. PLEs' *Int* is constitutively expressed, and upon infection by the helper phage ICP1, *Int* binds to the ICP1-encoded recombination directionality factor to catalyze excision. For PLEs 1,3,4 and 5 the recombination directionality factor has been shown to be *PexA*, which is uniquely encoded by ICP1 and underpins the specificity of PLE induction by ICP1. The recombination directionality factor required for PLE 2 *Int* is not yet known, though it is not *PexA*, and evidence points to it also being uniquely encoded by ICP1.

PICI and PLE gene expression is also responsive to the presence of their respective helper phages. Although it is unknown how exactly PLE gene expression is induced by ICP1 infection, induction of the Gram-positive PICI genetic program is well understood. Prior to infection or induction by a helper phage, Gram-positive PICIs, like SaPIs, are thought to be transcriptionally quiescent in the bacterial hosts' genome. A SaPI-encoded master repressor *Stl* prevents gene expression from the left and right SaPI operons. Upon infection by a specific helper phage, a phage-encoded protein disrupts the *Stl*-DNA complex, resulting in SaPI de-repression (Fig. 2). It is thought that Gram-negative PICIs use a different induction strategy than that of the Gram-positive PICIs. Rather than rely on a master repressor which is then de-repressed by a phage-encoded inducer protein, PICIs in Gram-negative bacteria use an *AlpA* activator to induce expression, though it is unknown how *AlpA* responds to infection by helper phage. The mechanism through which ICP1 triggers PLE gene expression is not yet known, but PLE gene expression appears to be dependent on the presence of ICP1.

The responsiveness of gene expression to the SOS response differentiates Gram-positive PICIs from Gram-negative PICIs and PLEs described thus far. The SOS response is a bacterial stress response, triggered by the presence of ssDNA that can be induced in the laboratory by bombardment with UV irradiation or treatment with certain drugs like Mitomycin C or antibiotics like fluoroquinolone. *LexA* is a global repressor of the SOS regulon, which comprises a large number of genes that are repressed by *LexA* in the absence of SOS induction. Once de-repressed, these genes change the state of the cell, resulting in the cessation of translation and cell division. For many prophages, a homolog of *LexA* directly represses the lytic pathway, maintaining the prophage in a quiescent state in un-stressed cells. *S. aureus* hosts that contain an integrated helper prophage that are sensitive to the SOS response can trigger the excision and de-repression of SaPIs upon SOS induction. SaPIs are therefore indirectly triggered by the SOS response to mobilize and horizontally transmit to naïve cells, creating a link between antibiotic treatment and increased spread of virulence factors. Expression of the Gram-negative PICI activator, *AlpA*, is not directly impacted by the SOS response,

however its expression is likewise dependent on a yet to be identified phage-encoded inducer, and so it is possible that AlpA-activated PICIs are also indirectly induced by the SOS response. *V. cholerae*'s PLEs are not thought to be induced by the SOS response, as their induction is specific to ICP1, a lytic phage, rather than temperate phage.

Upon phage-triggered induction and excision from the chromosome, PICIs and PLEs begin replicating. SaPIs utilize their own primase (Pri), replication initiation protein (Rep) and origin (*ori*) in conjunction with their host's bacterial DNA polymerase to replicate as DNA concatemers. PLE replication is likewise dependent on the PLE-encoded replicon comprised of an *ori* and a replication initiator protein RepA. A striking difference between PLEs and PICIs is in their dependence on phage-encoded products for replication: PICIs replicate autonomously, with their helper phage playing a primary role in transcriptional activation. For example, expression of the *pri-rep-ori* module on a plasmid is sufficient to drive replication of that plasmid in several Gram-positive hosts, indicating that host machinery is capable of replicating PICIs from Gram-positive and some experimentally validated Gram-negatives. In contrast, in PLE 1 (for which replication has been characterized), replication itself is dependent on ICP1-encoded products, indicating that PLEs have evolved to parasitize phage-encoded replication proteins. In support of the model of PLE-mediated replication hijacking, PLE replication is associated with decreased ICP1 DNA replication, whereas that has not been reported to be the case for PICIs.

Packaging and Horizontal Transmission

All satellite phage known to date use their helper phage's structural components to package and move their genomes to new bacteria in a form of transduction. Many SaPIs rely on modification, specifically re-sizing, of their helper phage's capsid. These smaller capsids are about one-third the size of helper phage capsids, and therefore are only able to accommodate the SaPI genome, which for many SaPIs is about one-third the size of the helper phage genome. Morphogenesis of a smaller capsid for SaPIs is accomplished by SaPI-encoded proteins, which can act as capsid scaffolds. Capsid modification is one mechanism SaPIs use to interfere with their helper phage (discussed further below).

PICIs, like all phages, use two strategies for packaging: a headful mechanism dependent on a terminase complex and *pac* site, or a *cos*-site dependent mechanism. Many sequenced PICIs of both Gram-positive and Gram-negative bacteria encode their own small terminase subunit, TerS, which recognizes the PICI encoded *pac* site, bringing it to the phage-encoded TerL subunit to preferentially package the PICI genome. However, several PICIs lack a TerS homolog, yet package and transmit at a high frequency. It was first shown that some SaPIs, such as SaPIbov5, utilizes both a headful mechanism for packaging as well as a *cos*-site mechanism. Indeed, PICIs that encode a phage *cos*-site are more common than initially appreciated, and are found in lactococci as well as in Gram-negative PICIs from *Escherichia coli*. PICIs that are packaged via *cos*-sites use an unrelated protein Ccm (for *cos* capsid morphogenesis) which interacts with the phage capsid protein to direct formation of smaller phage capsids to only accommodate the smaller SaPI genome, reducing the titers of helper *cos* phage. By bioinformatics analyses, several Gram-negative PICIs appear to encode for their own capsid monomer, potentially explaining how these PICIs are packaged into smaller capsids despite not possessing the genes *cpmAB*. *V. cholerae*'s PLE has been shown to transduce to naïve cells, but since few PLE-encoded gene products possess homology to any known proteins, there are no clear homologs of Ccm or CpmAB and the structural makeup and morphology of PLE transducing particles remains to be elucidated. Interestingly, the disparity in genome size between PLEs and their only known helper phage ICP1 is much greater than other PICI systems: the genomes of PLEs are one sixth the size of the ICP1 genome, so it remains to be determined if the same tactics used by SaPIs to redirect capsid assembly are utilized by PLE. Nonetheless, horizontal transfer of PLEs requires that the recipient cells possess ICP1's surface receptor, a component of the lipopolysaccharide O-antigen, suggesting that PLE transduction relies on ICP1 structural components. Regardless of how PLEs transmit themselves horizontally, they likely interfere with ICP1 particle assembly, since no infectious phage are produced following ICP1 infection of PLE-containing *V. cholerae*. It is likely a generalizable phage satellite strategy to steal packaging resources to promote horizontal transmission, as this ploy accomplishes both interference with the helper phage and promotes dispersal of the satellite phage genome.

Strategies PICIs Use to Interfere With Their Helper Phages

All PICIs discovered thus far confer a fitness benefit to their host bacterium by interfering with the propagation of their helper phages. As we have discussed, the co-dependence of PICIs on their helper phage for transmission means that natural selection would favor PICIs that only target vulnerable nodes in the phage lifecycle which are not self-defeating. Since most phage proceed through their lifecycle in a temporally regulated manner, where events late in infection depend on the success of those early in infection, PICIs have evolved not to interfere with early stages of their helper phage lifecycle, as they rely on the production of late gene products for their own transmission. PICIs therefore have finely tuned mechanisms that target assembly of their helper phage virions. In well-studied SaPIs three interference mechanisms have been described, and are used to varying extents by different SaPIs. First, as discussed above, SaPIs alter their helper phage capsids to produce smaller particles, restricting the packaging of the larger helper phage genome so that only the smaller SaPI genome can be packaged. Additional mechanisms of interference are found in the same gene cluster as the *cpmAB* operon (Fig. 1). A second mechanism further ensures that only the SaPI genome is packaged by targeting the helper phage terminase. The Ppi protein binds to the phage TerS, directly blocking the packaging of

helper phage DNA. Ppi does not interact with the SaPI TerS protein, ensuring that SaPI genome packaging proceeds uninhibited. A homolog of *ppi* is found in all sequenced SaPIs, as well as in several Gram-positive bacteria that have not been functionally shown to carry a satellite phage, indicating that additional phage satellites are waiting discovery. A third mechanism helps SaPIs interfere with certain helper phages through the PtiA, PtiB and PtiM proteins which interact with the helper phage late gene cluster. The late gene cluster in the helper phage genome encodes for structural components of the phage particles and host cell lysis. PICI helper phage regulate this late gene cluster by a member of the later transcription regulator" (Ltr) superfamily of proteins. The SaPI protein PtiA directly binds to LtrC to inhibit its activation of late gene expression. The gene immediately upstream of PtiA, PtiM, is co-translated with PtiA and acts as a modulator of the LtrC-PtiA interaction (Fig. 2). PtiM binds to PtiA, decreasing its ability to bind LtrC and allowing production of some structural components for SaPI packaging, as well as the lysis genes required for release of transducing particles. A third protein, PtiB, is known to interact with PtiAM, but is toxic to the host cell when expressed and its role in modulating late gene expression is not known.

As discussed above, available evidence suggests that PLEs also transmit horizontally using ICP1 structural components, although the molecular basis for PLE-mediated phage inhibition remains to be determined. PLEs may encode proteins with functions analogous to satellite phage that divert structural components to promote horizontal transmission, and those functions would likely also inhibit ICP1 assembly. However, there are several interesting differences between PICIs and PLEs that operate at the level of phage interference. The most striking of these differences is that PLEs completely block ICP1 production such that no new ICP1 progeny are produced during a burst assay. In contrast, SaPI1 reduces, but does not block, the reproduction of its helper phage 80 α in a comparable burst assay. This could indicate that all PLEs target several distinct assembly hubs, such that absolutely no ICP1 particles can assemble, and/or that the PLE-mediated decrease in ICP1 DNA replication compounds the effects on assembly to ensure that no ICP1 can overcome interference. It has also been observed that PLEs can accelerate cell lysis following ICP1 infection, which again may act in concert with other strategies to ensure complete inhibition of ICP1. PLEs appear to only provide a benefit to their *V. cholerae* host at the population level, as the infected cell always dies, but since no infectious ICP1 are produced, uninfected neighboring cells survive. In contrast to PLEs, PICIs known to target phage DNA replication or phage-mediated lysis have not been reported.

Prevalence of Phage Satellites

Satellite phage that use a helper phage to trigger excision and spread themselves through parasitizing phage structural components appear to be widespread in many Gram-positive bacteria that are important for human health and disease, such as staphylococci, streptococci and lactococci. In addition, a mobile genetic element in *Enterococcus faecalis*, EfCIV583, was recently shown to be functional and use Φ 1 as an inducing and packaging helper phage. EfCIV583 possesses many of the defining features of SaPIs (int/xis function, replication mediated by the elements Pri-Rep-ori cluster, repression by a master regulator Rpr), except that it lacks the TerS subunit that SaPIs use to direct packaging of their own genome.

In addition to PLEs in *V. cholerae*, a recent study has identified PICIs in several Gram-negative bacteria. Putative PICIs have been identified in several strains of *E. coli* and *Pasteurella multocida*, with their functionality demonstrated in *E. coli*, EcCICFT073 and EcCIO42, and from *P. multocida*, PmCIATCC43137. Several differences between Gram-negative and Gram-positive phage satellites suggest that they evolved multiple times in the different lineages. These studies likely underestimate the prevalence of comparable islands however, since bioinformatic approaches have relied on conserved genetic organization to identify PICIs in Gram-negative bacteria, and PLEs that have no known homology to any PICIs and they possess a distinct genetic organization (Fig. 2). Perhaps the earliest characterized phage parasite is the P4 satellite phage found in *E. coli*, which co-opts the phage P2 for key stages of its lifecycle. P4 relies on induction or infection by its helper phage P2 for activation and packaging, while encoding its own replicon. Familiarly, P4 interferes with P2 particle formation by altering capsid morphology to only allow successful packaging of the smaller P4 genome. The similarities between the P2-P4 system and the PICI-helper phage systems we have discussed here were once overlooked because of its distinct genomic structure from the Gram-positive SaPIs. However, as we have seen, the discovery of additional PICIs with alternative arrangements suggests that there is not one formula for a PICI, and the functional similarities between the P2-P4 system and known PICIs suggests these genetic elements should all uniformly be considered phage-satellites.

The convergent evolution of PICIs suggests that life as a phage satellite is a successful strategy to allow for genome reduction, and therefore, would be selected for in multiple bacterial hosts where infection by a specific phage is a reliable feature of the host's biology over time. Unbiased approaches to study genome flux following phage infection are needed to discover the true breadth of MGEs that harness phage for their own spread.

Counter-Evolution by Phages to Avoid Parasitism by Satellites

In the known cases of helper phage parasitism by satellite phages, the excised elements limit the spread of the helper phage – partially in the case of PICIs, or completely inhibiting ICP1 in the case of PLEs. This partial or complete inhibition of helper phage propagation exerts strong purifying selection on the phage to overcome parasitism by its satellite phage. As discussed above, expression of the majority of SaPI genes is under the control of the global repressor Stl. Helper phages de-repress SaPIs by producing a non-essential phage protein that binds to Stl to disrupt the Stl-DNA complex leading to induction of the SaPI

program. Interestingly, these inducing proteins are structurally unrelated, yet all interact with the *Stl* repressor to perform the same function. Helper phage can therefore overcome SaPI interference by acquiring mutations in the inducing protein. Sequence analyses of known SaPI inducing proteins have shown that they are under purifying selection, which, interestingly increases the allelic variance at this locus. Experimentally, *80α* encodes at least four anti-repressor proteins, one of which induces three different SaPIs that all have the same *Stl*: SaPI_{bov1}, SaPI_{bov2} and SaPI₁. Within three passages of *80α* on each of these SaPIs, phages that do not induce SaPIs are selected for, demonstrating that phage readily evolve mutations in the inducing proteins. Interestingly, although these proteins are not essential, phage that possess a mutant version of the SaPI-inducing protein are less fit than wild type phage in the absence of SaPI pressure. *Dut* is a phage-encoded dUTPase, which maintains low cellular dUTP relative to dTTP in order to prevent the introduction of uracil into DNA, and serves as the inducer for SaPI_{bov1} and SaPI_{bov5}. Between phages *Duts* show striking allelic variation and ability to induce SaPIs, suggesting the pressure to avoid inducing SaPIs has driven this diversification. Continued passaging of SaPIs with their mutant non-inducing helper phage results in selection for SaPIs that typically have a mutation in *Stl*, resulting in their constitutive expression which can be detrimental to their bacterial host. Phage-encoded inducer proteins and SaPIs are in a dynamic arms race, where a helper phage evolves resistance to SaPIs by mutating or losing the inducer gene (assuming the fitness costs are not too high relative to benefits). SaPIs then acquire mutations in their repressor so they are constitutively expressed in the absence of their helper phage, meaning they are unable to be packaged and spread by their helper phage. This removes the adaptive advantage that the mutant SaPI allele has and they are lost in the population, favoring again the SaPIs with compatible regulation which can then spread using their helper phage.

Despite many parallels between PLEs and PICIs in terms of mobilization by specific inducing phage and phage interference, induction of PLEs appears to show little functional similarity to the canonical SaPIs. PLE excision requires the previously described, ICP1-encoded gene product *PexA*. It is possible to generate $\Delta pexA$ ICP1 mutants in the laboratory that fail to catalyze PLE excision, however mutations in *PexA* are not seen in natural isolates of ICP1. *PexA* mutations are likely not selected for in nature however, because, surprisingly, PLEs still inhibit ICP1 without excision and circularization. In keeping with this observation, it has not been possible to successfully evolve ICP1 to avoid inducing PLEs *in vitro* with sequential passaging as has been done to study the SaPI-helper phage paradigm. These findings indicate that PLEs may have evolved to respond to several distinct ICP1-encoded inducers, such that ICP1 may not be able to overcome PLE-mediated inhibition through mutation and succeed in nature. However, PLEs do impose a significant evolutionary burden on ICP1 in nature as evidenced by some isolates of ICP1 acquiring an anti-PLE defense strategy in the form of a Type 1-F CRISPR-Cas system. Much in the way that CRISPR-Cas functions as an adaptive immune system to target foreign DNA for destruction in bacteria, the ICP1-encoded CRISPR-Cas system deploys CRISPR-RNAs transcribed from spacers that are complementary to PLE sequence to guide an effector nuclease to limit PLE activity. ICP1 is the first phage demonstrated to encode a functional CRISPR-Cas system, and such an unexpected evolutionary innovation highlights the significance of competition between a helper phage and its satellite in nature. The increasing prevalence of CRISPR-Cas⁺ ICP1 isolates in Bangladesh underscores the constant pressure ICP1 faces against PLEs in its *V. cholerae* host. Intriguingly, even though the ICP1 CRISPR-Cas system limits PLE replication, transmission and ICP1 interference, PLEs are still increasing in frequency in epidemic *V. cholerae* isolates, suggesting that although ICP1 has acquired a formidable weapon against PLEs, PLEs may still confer a fitness advantage to *V. cholerae*.

Consequences of Phage Satellites in Human Health and Disease

The first characterized SaPI demonstrated that phages spread the gene for toxic shock syndrome toxin to naïve *S. aureus* cells through mobilization of a genetic island that has come to be appreciated as a phage satellite. The majority of *S. aureus* virulence factors are found on SaPIs, including toxic shock toxin and other superantigens, in leftward and rightward accessory regions with their own regulatory regions (Fig. 1). Accessory genes can make the host bacterium more pathogenic by encoding for toxin production (such as the *tst* gene or enterotoxins EntQ and EntK). Other accessory genes can confer antibiotic resistance to aminoglycosides and Fosfomycin, or encode for multidrug transporters. Of other relevance in host-pathogen interactions are genes involved in iron transport and biofilm formation that have been found on SaPIs, which are important for successful colonization of human hosts and evasion of the immune response. In addition to SaPI encoded virulence factors, these phage satellites have been shown to transfer portions of the host chromosome between bacteria through generalized transduction. This can greatly accelerate the speed at which bacteria evolve within their human hosts.

With the rise of antibiotic resistance among human pathogens, there is renewed interest in phage therapy as a way of combating antibiotic resistant infections. Current interest in phage therapy has focused on lytic phages, which do not integrate into the host chromosome. Lytic phages are often considered safe because they are not likely to transduce genetic material from host to host through specialized transduction. This simplified view of the potential impact of lytic phages on promoting genomic flux is quite misleading. As highlighted in this article, lytic phages are capable of inducing and horizontally transferring mobile genetic elements. Although all known SaPIs and PICIs (for which helper phages have been identified) have evolved to parasitize temperate phages, PLEs in *V. cholerae* are mobilized by ICP1, a lytic myovirus. The dominance of temperate phages in mediating PICI mobilization is also likely an artefact of the ease at which temperate phages can be identified (*i.e.*, their genomes are present in single colony isolates) and not likely a biological constraint that prohibits MGEs from parasitizing lytic phages. When the lytic phage ICP1 infects a PLE containing *V. cholerae* cell, only PLE transducing particles are produced when the cell lyses, and PLEs can transduce to naïve *V. cholerae* transforming phage sensitive hosts to dead ends for future ICP1 attack. Phage therapy employing

ICP1 has been suggested as a viable means to limit cholera spread in endemic regions, though mechanistic insights demand caution as phage resistance and perhaps other beneficial phenotypes are likely to become widespread. The notion that employing CRISPR-Cas⁺ ICP1 to overcome PLE-mediated resistance in *V. cholerae* is likewise oversimplified, as CRISPR targeting of PLE can permit ICP1 replication while still allowing for some PLE transmission.

Conclusion

PICIs are widespread within both Gram-positive and Gram-negative bacterial hosts, playing a key role in host virulence and phage resistance. These satellite phages do not encode their own structural and lysis genes, but rather parasitize a helper phage for excision, induction, and packaging, and in the case of PLEs, also for genome replication. The reliance on a helper phage allows the satellite to reduce its genome size, suggesting that perhaps phage satellites evolve from defunct temperate phages. However, it remains possible that diverse MGEs evolve *de novo* to parasitize specific phages to promote their own dissemination. PICIs are functionally analogous to the so-called integrative plasmid P4, which acts as a phage satellite of the inducing phage P2 infecting *E. coli*. This strategy of genome loss and parasitism of a helper phage has evolved independently multiple times, and these phage satellites are likely present in diverse bacterial hosts that have not yet been characterized. Once more is known about how PLEs are induced and packaged, they may be included within the larger umbrella of PICIs. PLEs are not induced by SOS induction of their cognate helper phage, and it is unknown whether PLE encodes virulence factors.

With the discovery of CRISPR-Cas and the advent of a public health crisis caused by antibiotic resistant bacterial infections, there has been renewed interest in phage, as both tools for biotechnology and in treatment of bacterial infections through phage therapy. There are many unknowns in how bacteria respond to the constant pressure of phage predation, and even less known about how competing phage satellites battle for a bacterial host. The prevalence of PICIs indicates that phage infection can lead to unexpected outcomes, such as the spread of virulence, anti-phage and antibiotic resistance genes. With the increase in the number of sequenced genomes and improved bioinformatic pipelines, we will likely continue to find new genetic elements that parasitize phage through induction and co-option of replication and packaging materials. Discovery and investigation of PICIs and PICI-like elements will reveal how bacterial evolution can proceed at a pace unexpected by mutation alone – the acquisition of mobile genetic elements can dramatically re-shape the phenotype of their host in one generation. One consequence of acquiring a PICI is restriction of helper phage production when infecting that host. PICI interference can select for helper phage mutants or, in the case of ICP1, selection of phage that have acquired CRISPR-Cas to overcome PLE. This evolutionary arms-race between phage satellites and their inducing phage can yield unexpected outcomes, urging caution before applying the use of phage in treating bacterial infections.

Glossary

ATPase ATPase is an enzyme that catalyze the hydrolysis of the phosphate bond in adenosine triphosphate (ATP) to form adenosine diphosphate (ADP). The free energy harnessed from this reaction can be used to drive other cellular reactions.

Brownian motor The Brownian motor is a device that can do mechanical or electrical work at a nanometer scale. In the device, externally sourced energy is needed to generate fluctuating anisotropic energetic potentials. The anisotropic potentials provide forces that would bias the motion of a particle in one direction. Translocation of the particle would be a consequence of a unidirectional Brownian motion.

Capsid A capsid is the protein shell of a virus. It consists of several oligomeric structural subunits made of protein called protomers.

Coat protein A predominant protein in the capsid that can form tiny channels in the major capsid proteins so that only ions or water can pass through.

Concatemeric DNA The concatemeric DNA is a multimeric head-to-tail polymer of viral DNA that contains multiple copies of an entire genome linked in series. It serves as the substrate for the production of the relevant viral genome in a bacteriophage terminase during the DNA assembly.

Portal protein The portal protein is a dodecameric protein, located at the portal vertex. It serves as a conduit through which dsDNA is translocated during DNA packaging in tailed bacteriophages. In Phi29 bacteriophage, the portal protein is also named as connector.

Prohead A prohead, or procapsid, is an immature viral capsid structure formed in the early stages of self-assembly of some bacteriophages including tailed bacteriophages.

Scaffolding protein Scaffolding protein is the protein that directly reacts with the portal protein to help to form the empty prohead along with other proteins. After the formation of the prohead, this protein usually is expelled, leaving space for genomic DNA.

Terminase Terminase is a viral enzyme that usually consists of two subunits with different sizes. The small subunit recognizes viral DNA by binding a specific/nonspecific site on the concatemer. The large subunit, docking on the portal vertex, contains the ATPase activity that powers translocation of the viral genome into the prohead and the endonuclease activity that cuts concatemeric DNA to a single genome length.

The Donnan's effect The effect (also known as the Donnan law, Donnan equilibrium, or Gibbs–Donnan equilibrium) is used to describe uneven distribution of charged particles near a semi-permeable membrane. The usual cause is the presence of a different charged substance, e.g., DNA, that is unable to pass through the membrane and thus creates uneven electrical potentials across the membrane.

The head-tail connector In a mature virion particle, the head-tail connector usually refers to a protein complex composed of the portal protein, the adapter protein and the stopper protein, which connects the filled head to the tail.

The Tail (The tail protein complex) The bacteriophage tail is a molecular machine used during infection to recognize the host cell and ensure efficient genome delivery into the cytoplasm.

Introduction

The *Caudovirales*, an order of viruses, are known as the double-stranded tailed bacteriophages. Based on their tail morphology, they are divided into three families known as *Myoviridae* which have long contractile tails (e.g., phages T4 and P1), *Siphoviridae* which have long noncontractile tails (e.g., λ and SPP1), and *Podoviridae* which have short noncontractile tails (e.g., Phi29 and P22).

A major strategy that bacteriophages use in order to protect their genomic chromosomes from the environment is to pre-assemble icosahedral proheads (procapsids). By means of a powerful DNA packaging motor, viral genomes are subsequently pumped into the preassembled icosahedral heads through a viral portal protein located at a unique axis of 5-fold symmetry known as the portal vertex. The portal provides a unique site through which the viral genome enters and exits the prohead. Because both tailed bacteriophages and certain human pathogens in the herpesvirus family share the similar structural features, their DNA packaging process is assumed to originate from an evolutionarily conserved mechanism. Owing to the ease of operation in research, the tailed bacteriophage is typically used as a model system for studying this viral genome encapsidation mechanism.

In the past 50 years, the assembly mechanisms of several dsDNA bacteriophages have been investigated in depth where the experimental results have shown that the portal vertex is formed by a structurally conserved dodecameric portal protein which plays key roles in the viral chromosome packaging. Fig. 1 shows a typical, simplified viral assembly pathway where the portal protein is directly involved in the following major stages in a tailed bacteriophage:

Fig. 1 A Typical and Simplified Pathway for the Viral Assembly of a Mature Virion Particle.

Formation of a Prohead

In order to start the DNA packaging, an icosahedral prohead needs to be preassembled. Aided by scaffolding proteins, the monomer of the portal protein may polymerize and form a dodecameric portal ring. The portal ring may work as a reaction center where both coat proteins and scaffolding proteins associate to form a preassembled prohead. When the assembly is finished, the scaffolding proteins trapped inside the prohead may diffuse out or be degraded and will finally not be present in a completed virion.

DNA Packaging into the Prohead

In the majority of the tailed phages, a protein complex, terminase, is used to begin DNA packaging. The protein complex usually consists of two subunits: the large subunit (TerL) and small subunit (TerS). In the first step, TerS recognizes a concatemeric DNA substrate in which many copies of the viral genome are linked end-to-end. After the formation of the DNA-TerS protein complex, the TerL subsequently docks on the portal protein of a prohead. Under the action of the TerL ATPase, the concatemeric DNA is packaged into the prohead. When a genome length of DNA is completely encapsidated, the portal protein may signal to the TerL and activate the inherent endonuclease to cut the concatemeric DNA substrate at a specific site (e.g., λ) or nonspecific sites (e.g., T4, P22, SPP1) to stop the packaging process. The package mode with non-specific cleavages is named as the headful packaging.

Some tailed bacteriophages use different packaging modes. For example, in Phi29, the ATPase known as GP16, is equivalent to the ATPase on the TerL in other phages, but GP16 does not have endonuclease activity. The portal protein in the phage, however, is bound to a packaging RNA (pRNA), which can form a pentameric ring on the portal protein. The pRNA provides a binding site for the ATPase and is therefore considered to be evolutionarily associated with a part of the TerL. The DNA substrate for the ATPase contains one unit of the viral genome covalently bound by a protein (GP3) at both ends. The ATPase will stop the packaging process when the full genome is completely packaged into the prohead.

Virion Maturation

As the prohead is filled with DNA, the icosahedral lattice may expand to mature the capsid shell. Under the assistance of the portal protein, the packaged DNA is spooling-like and highly ordered. As the terminase is dismantled, the portal protein may close its

channel. Adapter proteins, stopper proteins, as well as the tail are subsequently assembled at the portal vertex, completing the maturation of a virion particle.

The Structural Features of the Portal Proteins

The subunits of the portal proteins can vary in molecular mass and amino acid sequence among the tailed bacteriophages shown in [Table 1](#). However, they share highly conserved structural features in the tailed bacteriophages, such as that the channel of the portal protein in the bacteriophages is always composed of 12 subunits. Whereas the portal rings may consist of 11–14 subunits (e.g., 12 mers and 13 mers can be found in the Phi29 and SPP1 portal proteins) when the portal proteins are purified and self-assembled in vitro. The inconsistency in the oligomerization state can also be found in the pRNA in Phage Phi29 where it is observed to have five subunits in the virion particles by cryogenic electron microscopy (Cryo-EM), while the in vitro assembly experiments showed that the pRNA is a hexameric RNA complex. The results indicate that the in vivo assembly of the ring structure in the portal proteins may need assistance from other components such as the scaffolding proteins ([Fig. 1](#)).

In addition to the 12-fold symmetry, the central channel of the portal proteins has a minimum 2.8 nm diameter at its narrowest constriction so that dsDNA has sufficient space to pass through. The channel in the portal looks similar to a truncated cone ([Fig. 2](#)) where the diameter of the channel for DNA entry is always smaller than the channel end for DNA exit in the packaging process. The amino acid residues in the interior wall of the channel are predominately negatively charged which may generate strong electrostatic repulsion against the DNA.

The subunit in the portal proteins in the tailed bacteriophages have similar core organization in its appearance, which can be divided into four domains ([Fig. 3](#)): the clip, stem, wing, and crown domains. A brief summary of the main functions of the conserved structural motifs is provided in [Table 2](#).

The clip domain: The domain consists of an α/β fold and may interact with adjacent portal subunits by hydrophobic interactions to stabilize the oligomerization state of the portal protein. The domain is exposed to the exterior of the capsid providing an interface when in contact with the coat proteins, provides the binding site for components in the DNA packaging motor, e.g., TerL, and also provides a site where phage tail attachment occurs.

The stem domain: This domain is sandwiched by two domains known as the clip and wing, which is featured with two well-conserved α -helices. The central channel in the dodecamer is surrounded by the 24 stem helices, which may impart structural plasticity and induce conformational changes during the DNA packaging. A conserved structure known as the channel loops is present in the stem domain. The channel loops have been shown to generate a constriction in the channel that prevents leakage of genomic DNA near the end of DNA packaging.

The wing domain: The domain is internal to the prohead and is above the stem domain. It is a globular domain whose size differs among tailed bacteriophages. The hydrophobic amino acid residues such as tryptophan, found in the domain can form a conserved hydrophobic belt around the exterior surface of the portal protein. This region is assumed to interact with scaffolding proteins to form the ring structure and initiate the assembly of the prohead. Owing to the presence of the hydrophobic belt, it is noted that the Phi29 portal protein can be readily inserted into a bilayer lipid membrane for channel property measurements and maybe potentially used for nanopore sensing technology.

The crown domain: The crown domain in the portal proteins of the tailed bacteriophages is located at the C-terminal in the primary structure of the subunit. The crown domain in the portal proteins of phages SPP1, T4 and P22 orients towards the center of the capsid, which is directly in contact with the packaged DNA inside the capsid. The structure of the crown domains has some variations among certain tailed bacteriophages. Due to the flexibility, the crown domain of the portal proteins in some phages, e.g., Phi29, cannot be directly visualized in crystal structures or in Cryo-EM images. On the other hand, in the portal protein of P22, a 20 nm left-handed coiled-coil helical barrel is found to extend from its crown domain. Site-directed mutation studies have shown the barrel may even be involved in the organization of the spool-like DNA structure inside the capsid.

Table 1 A Comparison of the Primary Structures of Several Portal Proteins in the Tailed Bacteriophages

Phage Family	The Virus Name	The number of Amino Acids in a Protomer	The I.D. in the PDB Database
Podoviridae	Phi29	309	1FOU, 1JNB, 1IJG, 1H5W
	P68	327	6Q3G
	T7	490	6QWP, 6QX5, 6QXM, 3J4A
	P22	725	3LJ5, 4V4K, 5JJ3, 5JJ1
Myoviridae	T4	455	3JA7
Siphoviridae	SPP1	503	2JES
	G20C	426	4ZJN, 5NGD, 6IBG

Note: Only the portal proteins whose 3-D structures are available in the RCSB Protein Data Bank (PDB) are included in the table.

Fig. 2 The Structure of the Portal Proteins Available from the PDB Database.

Functions of the Portal Proteins

The Viral Portal Protein as a Nucleator in the Assembly of the Prohead With Proper Morphology

The prohead assembly occurs at the earliest stage in the DNA assembly of the tailed bacteriophages. Three major proteins are involved in the process: the portal protein, the scaffolding, and the coat proteins. The portal protein functions as a nucleator and the scaffolding proteins may work as assembly chaperone to bind the subunit of the portal protein to assist the oligomerization of the subunits forming the ring structure. The conserved structure, a hydrophobic belt encircling the portal ring at the wing domain, may provide a site where scaffolding proteins bind to the portal protein. After the formation of the portal protein-scaffolding protein complexes, coat proteins then copolymerize with the scaffolding proteins. As copolymerization proceeds, the shell of the prohead grows around the portal ring. Relevant experiments show that more portal rings results in higher yield as well as the rate of prohead assembly. In addition, the portal ring was also shown to be capable of correcting the morphology of viral particles even in the presence of a high ratio of scaffolding protein vs coat proteins.

When the copolymerization ends, the scaffolding proteins may diffuse out of the prohead or may be degraded and finally exit out of the prohead making room for incoming genomic DNA. During the process, the portal protein may act as an exit for scaffolding proteins or their degraded products. The above mechanism can be used to explain why only one portal ring is found at a unique portal vertex in the capsid of the tailed bacteriophages.

Portal Proteins Provide Binding Sites for Terminases

The clip domain is a conserved structure, protruding out of the capsid in the exterior and is the site where the large subunit of the terminase protein (TerL) can bind. For example, in phage T4 the clip domain of the T4 portal binds to the C-terminus of the TerL. After the terminase is bound, genomic DNA will translocate into the prohead in an ATP-dependent process driven by the TerL ATPase. Some tailed bacteriophages differ in the binding process, for example, in Phi29 the clip domain on the portal protein

Fig. 3 The Conserved Structural Motifs in the Monomers of the Portal Proteins Available at the PDB Database.

provides a binding site for a pentameric pRNA. The ATPase known as GP16 (equivalent to the TerL in other bacteriophages) docks on the pRNA and self-assembles a ring structure around the pRNA to package the DNA into the prohead.

Portal Proteins Bound With Adapter Proteins Facilitates Tail Attachment

At the end of DNA packaging, after terminase protein dissociates from the portal protein, the clip domain of the portal protein would be converted to be an interface where the adapter proteins dock and subsequently the stopper proteins are attached in order to plug the channel to prevent the genomic DNA from accidental leakage.

The protein complex, composed of three proteins (the dodecameric portal protein, adapter proteins and stopper proteins), forms a knob-like structure at the portal vertex, which is used to connect prohead and the viral tail. Because of this function, the protein complex is also named as the head-tail connector which provides a site for attachment of the tail. It should be noted that, in the literatures about Phi29, the term connector only refers to its portal protein, also known as GP10.

Portal Proteins Help to Spool Condensed Genomic DNA in the Capsid to Form a Highly Ordered Structure

The packaged DNA in the capsid can be condensed to a highly dense concentration, about 500 mg/mL, and images from Cryo-EM experiments have shown that the chromosomal DNA in the capsids are highly orderly packed like liquid crystals. The highly ordered structure would prevent the chromosomal DNA from the entangling between the DNA segments, and subsequent DNA ejection would benefit from it.

The arrangement of the trapped DNA, however, varies among different tailed bacteriophages. For example, T4 DNA is arrayed longitudinally to the head-tail axis and both packed ends are located in the portal protein, whereas in T7 the packed DNA is spooled horizontally around the head-tail axis of the portal protein. The formation of the highly ordered structures of the packed chromosomal DNA in the capsid is assumed to be associated with the crown domain in the portal protein. However, how the domain is involved to spool the DNA into different structures is still unknown.

In P22, the portal protein is unique as both the crown domain and its extension, a coiled-coil alpha helical barrel structure, can be visualized clearly in the protein 3-D structure. The barrel is assumed to interact with genomic DNA and help the genome spool onto the interior surface of the capsid during genome packaging, working like a rotary sprinkler. To facilitate DNA ejection, the domain can also provide a docking site for ejection proteins and assure DNA ejection without tangling. In the phages that do not have the barrel structure, ejection proteins can assemble to a proteinaceous core bound onto the portal crown domain. The

Table 2 The Main Functions of the Conserved Structures in the Portal Proteins Among the Tailed Bacteriophages

	Provides a site for the docking of pRNA, that is subsequently bound to the ATPase.	Phi29 portal protein

resultant tunnel created by the stacked proteins, similar to the barrel structure in P22, is assumed to spool the DNA in a highly ordered structure inside the capsid.

Portal Proteins as a Check-Valve Preventing DNA From Slipping Out

A DNA packaging motor transports the viral DNA into the procapsid against a pressure of up to 20–60 atm, and thus a check-valve mechanism is needed to prevent the genomic DNA from slipping out of the prohead. Using the molecular dynamics simulation for the Phi29 portal protein as well as the relevant in vitro viral assembly experiments, three positively charged residues (K234, K235, and R237) on the structurally conserved channel loop are shown to play a crucial role in the check-valve mechanism. As the pressure is increasingly built up inside the prohead, the positively charged amino acids may intensively interact with genomic DNA to prevent it from slipping out. Based upon the structural observation, it is noted that another two rings of positively charged lysine residues (K200 and K209) located on the clip domain in the channel of the Phi29 portal protein are also assumed to be involved in the check-valve mechanism.

The existence of the check-valve mechanism was evidenced in an in vitro T4 DNA packaging experiment measured by optical tweezer. The experiments have found that the terminase proteins did not grip the portal protein strongly when ATP was hydrolyzed into ADP. Under the situation, the T4 portal tunnel loops are assumed to strongly “grip” the DNA to prevent it from slipping out. Similarly, the lysine residues (K331 and K342) in the SPP1 portal protein are also proposed to have similar gripping functions during the DNA packaging.

Portal Proteins as a Sensor to Control the DNA Packaging

In bacteriophages T4, P22, T1, P1, and SPP1, all follow the headful packaging mechanism in which the DNA packaging proceeds until a threshold amount of DNA is reached inside the viral capsid. When the prohead is filled in full, a high internal pressure is maintained. As a result, the high pressure may induce the conformational changes at the clip domain in the portal protein where TerL is docked. The TerL endonuclease is subsequently activated to cleave the DNA concatemer and generate a segment of DNA that contains one unit of the phage genome. In the process, the portal protein serves as a packaging sensor that may use the pressure in the capsid to regulate the maturation process of the capsid. The relevant mutation experiments on the phage P22 portal protein further suggest that the sensor could be located on the barrel of the portal protein.

In Phi29, near the end of DNA packaging, the portal protein may act as a pressure sensor, meaning it can change its conformation to detach the bound pentameric pRNA associated with ATPase. The portal protein is believed to use the conserved structure, the channel loops (residues 229–246), located in the channel interior as a clamp to retain the genomic DNA within the prohead before the tail components are attached. In an optical tweezer experiment on the Phi29 DNA packaging motor, the packaging sensor in the portal protein was assumed to sense the changes in the density and conformation of the packaged DNA at the late stage of DNA packaging. As a result, the activity of the ATPase would be allosterically regulated.

The Portal Proteins Actively Assists DNA Packaging Coupling With ATP Hydrolysis

The terminase-driven mechanism plays a key role at the initial stage of DNA packaging

When DNA enters an empty prohead or a prohead with a low pressure, terminase plays a central role in DNA packaging. A terminase-driven model is proposed to explain the process. The terminase is a hetero-oligomeric complex, composed of two subunits, TerS and TerL. TerS selectively binds the viral DNA concatemer from a pool that includes the host DNA. TerL uses its endonuclease to make a cut and binding itself on a portal vertex of the head to initiate DNA packaging.

The TerL is assumed to form a pentameric ring around the portal protein. The ATPase on each of the five subunits in the TerL may also have a domain that is responsible for DNA gripping. A section of genomic DNA is gripped in the center of the TerL ring when ATP is bound to all five subunits. ATP hydrolysis occurs at one subunit at a time. When the ATPase on one subunit is fired to hydrolyze ATP, the subunit alters its conformation to release DNA and then initiate motion that is transmitted to the adjacent ATP bound subunit, which is still gripping the DNA. The conformational changes of the ATP-hydrolyzing subunit results in an upward translocation motion of DNA at the adjacent subunit. The sequential interlaced ATP hydrolysis/binding on each of the TerL subunits may lead to unidirectional DNA translocation, which requires the activities of the individual subunits are highly coordinated. The terminase-driven model can be used to explain the 2.5 bp translocation per ATP measured for the Phi29 motor at low packaging force by optical tweezers.

The portal proteins actively assists DNA packaging at the late stage of DNA packaging

DNA packaging is an energetically unfavorable process. At the late stage of DNA packaging, a large amount of free energy is used to package DNA to overcome the high pressure in the prohead. In addition, energy is also consumed to assist the genomic DNA to form a highly ordered structure similar to a liquid crystal state in the capsid (an entropy-decreasing process). Images from Cryo-EM have shown that the portal proteins in all bacteriophages undergo conformational changes during the DNA packaging.

These conformational changes may have three possible origins:

- (1) They may be induced by the interior pressure in the capsid as discussed above;
- (2) They may be associated with the mechanical cycles of the ATPase during ATP hydrolysis;
- (3) The conformational changes may cyclically occur during packaging, and could be induced by the electrochemical potentials across the capsid shells.

On how the portal protein uses conformational changes to assist packaging, a handful of models have been proposed, which can be roughly categorized into two modes: portal directly-mediated packaging mode vs portal indirectly-mediated packaging mode.

The portal directly-mediated packaging mode

The ATPase in the terminase uses energy from ATP dephosphorylation to generate movement by mechanical cycles. The moving and pushing by the ATPase on the terminase may induce conformational changes in the portal proteins because TerL is directly docked on the portal protein. In the portal directly-mediated packaging mode, the resultant conformational changes are assumed to directly apply forces to the genomic DNA and push it into the procapsid.

Different models have alternate explanations to the conformational changes, thus the description about the DNA packaging process assisted by the portal protein varies among models. Several models categorized under the mode are highlighted below:

Rotation of the portal protein may apply forces to DNA

Because the portal protein has a 12-fold symmetry and it is located at a vertex with 5-fold symmetry, the model assumes that the asymmetry may facilitate the rotation of the portal protein at the viral vertex. In this model, the energy from ATP hydrolysis was assumed to rotate the portal protein which may screw the helical DNA into the capsid like a bolt moves on a nut. However, this model has been discarded currently due to recent experiments proving that the portal protein does not rotate during DNA packaging.

Lengthwise channel expansion and contraction in the portal protein may apply forces to DNA

The connector expansion and contraction model is based on the structural observation of the portal protein in Phi29. The portal protein is assumed to have plasticity and its channel may experience lengthwise expansion and contraction after the portal protein is slightly rotated by 12 degree when ATPase is activated. The movement in the model is described like a helical spring pumping the chromosomal DNA into prohead.

Sequential movement of tunnel loops may apply force to DNA

The model is proposed on the structure of the portal protein in SPP1. The SPP1 portal is found to have 12 long flexible loops that project into the central channel of the portal. These loops are a conserved structure among other portal proteins. They are assumed to tightly fit the DNA during the packaging. When the portal protein slightly rotates in coupling with ATP hydrolysis, the loops may undergo sequential movement, like an undulating belt. The DNA then moves sequentially along this belt and is packaged into the prohead.

In summary, the models following the portal directly-mediated packaging mode are proposed based on the structural observation of the portal proteins from the Cryo-EM or X-Ray Crystallography. However, the descriptions in the models about how the portal protein apply the forces to assist the DNA packaging as well as how the ATPase uses its mechanical cycles to induce the channel conformational changes have not been visualized experimentally.

The portal indirectly-mediated packaging mode

In this mode, the portal protein is proposed to work like an energy transducer. The energy from cyclic and random conformational changes in the portal is converted to a different energy form that is subsequently used to pack genomic DNA into the capsid. Two physical models that use the indirectly-mediated packaging mode are highlighted here:

DNA translocation driven by the energy from the DNA deformation in the portal protein

This model, named as the scrunchworm model, is based upon molecular dynamic simulation on the portal structures of P22, Phi29, and T4. The simulation assumes that sufficiently large conformational changes in the portal proteins can cause the DNA in the portal channel to undergo conformational changes between stretched and relaxed states. When DNA is in its extended form, the portal protein needs to grip the DNA at the bottom of the channel through electrostatic interactions and release the rest of the DNA at the top. When DNA is packaged in its shortened form, the top of the channel may grip the DNA and the bottom grip would open. The portal protein cyclically changes its conformations and applies force to store the energy of the DNA deformation. Like a spring, the DNA would be compressed and released back and forth, propelling the DNA into the prohead. Apparently, the process simulated in silico requires that the ATPase alternately changes the conformations of the portal protein in a well-controlled manner and this hypothesis needs to be further studied experimentally.

DNA translocation driven by a brownian motor inherent in the portal protein

In this model, the truncated cone structure of the portal protein ensures that the electrostatic interactions between the DNA and the negatively charged residues in the interior of the channel along the direction of DNA movement are asymmetrical. The ATPase continuously packages the DNA into the capsid and results in an increase in the electric potentials across the semipermeable capsid shell membrane called the Donnan's effect. This is the direct energy source for the Brownian motor where the electrochemical potentials can alternately change the channel conformation. Consequently, the portal protein works as a power rectifier, by which the asymmetrical and cyclic interactions between the portal channel and DNA would ratchet the DNA Brownian diffusion back to the channel bottom, and ensure the unidirectional Brownian motion towards the prohead.

The Brownian motor model is proposed based upon planar lipid bilayer membrane (BLM) experiments, in which the channel of the portal protein of Phi29 was shown to randomly and cyclically change its conformations under membrane potentials when the protein was embedded into a lipid membrane. Although the BLM results come from those measured by indirect experimental methods, they strongly suggest that the high probability of the existence of channel fluctuation under the membrane potentials. The Brownian motor model has successfully explained many experimental results from optical tweezers. For example, why the DNA packaging motor operates in a dwell-burst fashion and how it is affected at the late stage of DNA packaging. More importantly, the BLM experiments indicate that, besides the mechanical cycles of the ATPase in the ATP hydrolysis, the membrane potentials on the prohead shell may also play a role in inducing the conformational changes cyclically and alternately in the portal proteins.

Main Techniques Used to Study Portal Protein Structure and Function

Biochemical methods

Biochemical methods are traditional ensemble methods where a mutant component, e.g., the prohead containing a mutant portal protein, is usually designed and prepared using molecular biological methods such as site-directed mutagenesis. The mutant proheads are then mixed with other components for in vitro DNA packaging experiments. By means of enzymes such as DNase I and proteinase K, the size of the DNA packaged inside the capsid can be quantified. The conversion efficiency from filled prohead to phage can also be determined by mixing packaging solutions with bacteria for virus quantification. The methods are often used for investigating the functions of specific domains, e.g., the channel loops, in the portal proteins of the tailed bacteriophages.

Techniques for structural analysis

Two useful structural analysis methods are usually used in Structural Biology: X-Ray Crystallography and Cryo-EM.

In X-Ray Crystallography, the target protein needs to be dissolved in an aqueous environment. When the resultant sample solution reaches its supersaturated state, it may form a single-crystal form under precisely controlled conditions. In the process,

many factors may affect the growth of the protein crystal such as pH, temperature, ionic strength, and even gravity. Once properly developed, these crystals can be used in structural biology to study the molecular structure of the protein. Although X-ray crystallography can provide 3-D protein structure at atomic resolution, the process for protein crystallization may pose a great challenge to the study of portal proteins since many of them are known to be hydrophobic and may aggregate in the aqueous solutions. Another problem with the X-ray crystallography is that the structure of the portal proteins in its crystal form is not necessarily the same as the conformation during DNA packaging.

Cryo-EM can overcome some of the limitations found in X-ray crystallography. The method uses rapid freezing of solutions containing virions or virion components in which the intact structures of the biological macromolecule complexes can be preserved for electron imaging. The 3-D structure of a virus particle in its native conformation can be reconstructed by means of the combined images of virion particles using an image-processing software. The Cryo-EM can provide virus structures at sub-nanometer resolution and therefore is a very useful imaging tool to infer the information about how different motor components move and interact with each other.

However, Cryo-EM only provides snapshots representing the average of large ensembles of individual virion particles, thus upon freezing, the DNA packaging motors in different virion particles would be stalled in different stages of the enzymatic or mechanical cycle. The conformational heterogeneity would be an obstacle for Cryo-EM to directly visualize the conformational change of the target components as well as the relevant interactions at different stages, e.g., how the terminase proteins interact with the portal protein to induce its conformational changes during ATP hydrolysis.

The optical tweezers: a technique to observe DNA packaging in real time

Optical Tweezer is a technique that uses a focused laser beam to trap a micron-sized plastic microsphere in an optical microscope. In the single-molecule studies of viral DNA packaging, a single DNA molecule is tethered to the dielectric microsphere. When the tethered DNA is packaged into a capsid, the position of the trapped microsphere is also changed, which can be detected with great precision by imaging the light scattered by the microsphere. The light sensed by a position-sensitive photodetector can be used to provide sub-nanometer resolution of displacements and subpiconewton resolution of forces. The viral DNA packaging in phages, such as Phi29, T4 and lambda, have been studied in real time and the forces exerted by the motor on the DNA and the translocation dynamics can be measured. The measurement is performed at the single-molecule level, and therefore can provide the information that the ensemble methods cannot provide, for example the dwell-burst phenomena found in the DNA-packaging.

Molecular dynamics simulation

Molecular dynamics simulates the natural motion of molecular systems. The energy provided in a molecular dynamics procedure allows the atoms or molecules to interact for a definite period of time, providing a view of dynamic evolution of the molecular system e.g., the patterns, strength, and the behavior of the target components under various conditions. In the study of viral portal proteins, the methods were usually applied to the interactions between DNA and the amino acid residues on the interior surface of the channel in the portal proteins including Phi29, T4, and P22. It has been shown that, under the influence of sufficient and cyclic conformational changes in the channel of the portal proteins, the DNA can be unidirectionally transported into the capsid.

Planar bilayer membrane (BLM) technology

According to the Brownian motor model, the portal protein in the bacteriophage can fluctuate under the influence of the membrane potentials and high pressure in the capsid (the Donnan's effect). The resultant conformational change may play a critical role to ratchet the Brownian motion of DNA. Because the virion particles are too small (nanometer sized), the patch clamp cannot be used to measure the channel fluctuation under the in vivo potentials across the capsid shell. Therefore, BLM technology would be the only available experimental method that is used to indirectly visualizes the conformational changes on the portal protein under membrane potentials. In the method, a portal protein needs to be inserted into a bilayer lipid membrane. Under the influence of the Donnan's effect, the protein may fluctuate in response to the applied membrane potentials. The BLM technology can be potentially used to look for the domains in the portal protein that are involved in the sensing of the membrane potentials as well as in the channel fluctuation.

Concluding Remarks

The portal protein plays a core role in the packaging of the DNA of tailed bacteriophages. At the beginning stage, the portal protein is a nucleator to initiate the copolymerization of coat and scaffolding proteins to form an empty prohead with a unique portal vertex containing a dodecameric portal ring. The portal protein provides binding sites for terminase protein for packaging chromosomal DNA and for the adapter proteins for the installation of the tail. To prevent the DNA from tangling in the capsid, the portal protein may help DNA form a highly ordered structure. Because of the proximate contact with the DNA in the capsid, the portal protein may serve as a packaging sensor to participate the regulation of ATPase activity and transmit a signal to the terminase to dissociate from the capsid when DNA packaging is completed. As the pressure inside the shell increases, the portal can also serve as a clamp to prevent DNA from leakage near the end of DNA packaging. Because it has a flexible structure, the

portal protein may change its conformation cyclically and assist the DNA packaging in the portal directly-mediated packaging mode or the portal indirectly-mediated packaging mode.

The conformational changes in the portal proteins are assumed to play critical roles in the control, regulation and assistance of DNA packaging. How the conformational changes occur *in vivo* and what energy source is used to induce the conformational changes still lack direct experimental evidence. Therefore, the *in vivo* conformational changes are described differently in many models. In addition, the current experimental techniques are not perfect in providing the relevant experimental evidence. For example, the methods for the structural analysis, e.g., Cryo-EM, cannot provide details about how the terminase hydrolyze ATP in its mechanical cycles to induce the conformational changes in the portal proteins. The molecular dynamic simulations, in addition, cannot answer whether the sufficient conformational changes that cause the deformation of the DNA in a precisely controlled manner can still occur when the portal protein is embedded in the capsid shell composed of coat proteins. BLM technology is only an indirect method to measure the channel's conformational changes in a non-native environment. Optical tweezer measurements have never been used for the force measurement of DNA packaging when the viral assembly happens in a prohead containing a mutant portal protein. The integration of the available experimental techniques therefore is necessary in exploring how the portal protein changes its conformation in the tailed bacteriophages under influence of the pressure, ATPase and the membrane potentials as well as the roles that the resultant conformational changes play.

It has been known that mammalian dsDNA viruses, such as human herpesviruses, package their genome through their portal proteins using the similar mechanism that the tailed bacteriophages use. The structure of the portal proteins in human herpesviruses also share the common features with the bacteriophage portal proteins. The relevant study on the roles of the portal proteins in viral assembly in the tailed bacteriophages would provide very useful information for the preclinical studies that target the portal proteins in the human herpesviruses.

Glossary

Capsid The protein shell that contains and protects the genetic material of a virus.

Capsomer A pentameric or hexameric sub-assembly unit of the capsid.

Icosahedron A regular polyhedron with 20 equilateral triangular faces. Each face consists of 3 equivalent smaller triangles such that an icosahedron is made from 60 identical asymmetric subunits.

Maturation The process by which a prohead transforms into its more stable mature form.

MCP The Major Capsid Protein, multiple copies of which are arranged as capsomers to make up the shell that protects the phage genome.

Quasi-equivalence The slight difference in bonding patterns and conformations assumed by different individual MCPs in the asymmetric units of icosahedra with T-numbers greater than one.

Triangulation number (T-number) The number of additional triangles each of the 60 icosahedral asymmetric subunits can be divided into. Thus, the total number of MCPs will be $T \times 60$.

Introduction

The need for viruses to convert the limited resources of their host cells into the greatest number of progeny in the shortest time represents an optimization problem. Billions of years of evolution have produced a surprisingly small set of general solutions to this problem in the form of ‘assembly pathways’, i.e., the sequences of reactions and products that result in infectious virions. The most successful pathway, in terms of numbers of infectious particles, is that of dsDNA bacteriophages. A notable feature of this pathway, shown in Fig. 1, is that it goes through a structurally distinct intermediate en route to the assembly of mature infectious virions. This extra ‘prohead’ step allows efficient construction of environmentally stable protein capsules, or capsids that contain and protect the viral genome. The prohead is formed when hundreds to thousands of copies of the protein building block of the capsid, the major capsid protein (MCP), self-assemble into a fully enclosed shell. After its completion, the prohead transforms into the next intermediate in the assembly pathway, the mature head. To successfully complete the self-assembly pathway, MCP has conflicting requirements; weak binding is initially needed such that MCPs can detach and re-attach as necessary to correct for errors that may occur during prohead self-assembly, yet strong binding interactions are ultimately required to construct a robust mature capsid that can survive the extracellular environment. This conflict is resolved by an MCP that has evolved to adopt distinct conformations appropriate for the two separate requirements. The prohead state coordinates the transformation between these two conformations so it only occurs after all MCPs have assembled into the correct geometry. Understanding how these complex molecular rearrangements are regulated and coordinated at the atomic level will inform antiviral drug development, engineering of gene therapy vectors, and rational design of nanomaterials and catalysts, among other applications.

Understanding of the viral lifecycle requires a consideration of the evolutionary pressures that influence it. Competition for resources between a virus, its host, and its rivals favors genetic efficiency. Hence viruses generally have small genomes that produce a limited number of multi-functional proteins that can rapidly assemble the structures needed to construct an infectious virus.

Fig. 1 Assembly Pathway of tailed dsDNA bacteriophages. A simplified assembly pathway for the tailed-phages is shown. In A, soluble capsid protein (blue wedges), scaffold protein (yellow rods) and portal complexes (pink cone) begin to associate. In B, these components have assembled into a closed shell, the prohead. In C, the scaffolding protein has decoupled from the capsid protein, which expands into the mature head. The packaging motor (orange shape) has attached to the portal and begun to feed DNA (purple coil) into the capsid. In D, the capsid is filled with DNA, the motor has detached, and the tail and accessory proteins have bound to the capsid, resulting in the mature, infection-competent virion.

Viral capsids are therefore made of many copies of one or a few types of proteins that bind together to produce large MDa-scale macromolecular assemblies. Viruses generally, and bacteriophage especially, have limited access to sophisticated methods of component segregation, including a means of controlling the extent and timing of component movements. Typically, the protein components that assemble the virion must all coexist in solution simultaneously and perform their various tasks in the proper sequence, without interfering with one another. Double-stranded DNA bacteriophages avoid interference by assembling different structures as separate functional units called the ‘head’ and the ‘tail’, which contain/protect the viral genome and deliver that genome into the host cell, respectively. Because of these ‘tail’ structures, dsDNA bacteriophages are often referred to as tailed-phages. The ‘head’ structure is thus a context-specific term for capsid and is not typically used for viruses that lack tails. In the tailed-phage assembly pathway an empty prohead, or procapsid, is assembled first. A phage-encoded molecular motor then assembles at a unique vertex of the prohead and actively pumps the phage’s genomic DNA into the head. In many phages, DNA packaging is believed to trigger a series of structural changes that transform the prohead to mature head. After packaging is complete, the motor disassembles, and then the tail and related structures replace the motor at the unique vertex to complete assembly of the infectious virion.

All tailed-phage heads are icosahedral in shape. A standard icosahedron has 20 equilateral triangular faces and twelve vertices where 5 triangular faces meet. Some capsids are prolate, meaning that they are elongated along one axis and 10 of the 20 triangular faces are elongated and no longer equilateral. Icosahedral shapes are common among many different types of viruses because icosahedra have the greatest symmetry of any regular polyhedron; of the shapes that can be built from identical subunits, icosahedra use the largest number of subunits (60). Since a large number of subunits are used to construct an icosahedral capsid, the size of individual MCP subunits necessary to encapsidate a given volume can be smaller. Hence, an icosahedral capsid built from 60 copies of the MCP results in a large ratio of internal volume to encoding sequence length. Despite the genetic economy provided by high symmetry, an icosahedral capsid built from 60 copies of the MCP is not large enough to enclose the full genome of dsDNA bacteriophages, which must also code for proteins for the tail, DNA replication, DNA packaging, and other genes. Rather than simply coding for a larger MCP, tailed phages have evolved to build larger icosahedral capsids by using more than 60 copies of the MCP. To accomplish this while still maintaining overall icosahedral symmetry, phages have evolved to have more than one copy of the MCP in each of the 60 identical asymmetric units (ASU) in the icosahedron. The number of MCP copies in each asymmetric unit is called the triangulation number of the icosahedron. An icosahedral capsid with only one copy of the MCP per ASU has a triangulation number of $T = 1$ and a total of 60 MCPs per capsid, whereas a $T = 7$ capsid has $7 \times 60 = 420$ MCPs in total. While each individual copy of the MCP in the ASU has the same amino acid sequence, their structures are only quasi-equivalent, that is, similar but non-identical. It is important to note that the increased volume-to-sequence ratio gained by adopting quasi-equivalence comes at a cost. Because the quasi-equivalent structures are slightly different, they are capable of interacting differently with their neighbors. Thus, while an MCP capable of binding together in different ways can produce larger icosahedra, it is also capable of producing an infinite variety of other shapes, very few of which will allow the virus to infect new hosts, and none of which are optimal. Further challenges arise when we consider that infectious virions must attach the tail to the capsid. As discussed above, icosahedra have 12 vertices, and in tailed-phage capsids 11 of these are occupied by pentamers of MCP while the 12th is a unique vertex occupied by a ‘portal’ complex which allows DNA to enter and exit the capsid. Viral particles that incorporate more than one portal vertex, or none at all, will have reduced or no infectivity.

Despite the simplistic description we have given of the phage assembly pathway, in practice a large number of sequential steps and intermediate states are involved. While the overall pathway is consistent among tailed phage species, differences in host environment, infection strategy, genome size, and other factors result in variations in individual states and sequences in assembly. Only the most stable intermediates from these have been isolated and characterized. Further, the specific intermediate used to represent the ‘prohead’ state in one phage may not be a direct analog of the ‘prohead’ state of another. The term refers collectively to states in which MCP monomers have been assembled and arranged to form a fully enclosed shell, but have not yet transformed into the characteristic, highly stable mature conformation. All studied prohead states share a few common characteristics, and the “variations” observed may in fact be present in other phages but too short-lived to have been characterized. Common features of known prohead states include (1) the presence of a “scaffolding” protein that will not be present in the mature virion, (2) a smaller, more spherical shape than the mature heads, (3) a rougher or more wrinkled surface than mature state, and (4) the ability to bind a packaging motor at the unique portal vertex. Because of the large morphological differences among individual phages and the prohead’s nature as an intermediate state, understanding it is best served by describing features in relation to the mature virion. Hence, these and subsequent features of proheads are described relative to the mature head.

The more angular icosahedral shape of the mature capsid results from the need for tight inter-MCP binding and a high volume-to-sequence ratio. Similarly, the different shape of the prohead is the result of constraints associated with a different set of requirements, i.e., self-assembly of a closed icosahedral shell and incorporation of a portal vertex that, by its very nature, is inconsistent with the otherwise icosahedral symmetry. The sets of requirements of thermodynamic stability in the mature head and kinetically accessible meta-stability in the prohead are conflicting, yet both must be satisfied by the same protein, the phage MCP. The capacity to resolve this conflict is provided by an MCP protein fold capable of adjusting its three-dimensional structure according to the requirements of both quasi-equivalence and the particular step in the phage’s assembly pathway. While significant variations of the MCP occur across all known tailed phages and herpesviruses, the canonical MCP fold, shown in [Fig. 2](#), is always recognizable despite very little sequence conservation. The fold was first described in the *E. coli* phage HK97, which, coincidentally, also best represents the essential structural core. Extra features and embellishments are present in all subsequently determined structures of phage MCPs, and in herpesviruses account for the majority of the MCP fold. To describe the general structure and function of the prohead state, it is necessary to refer to features of this conserved MCP structural core. Briefly, the HK97 protein

Fig. 2 The HK97-like fold of the MCP. This illustration of an idealized MCP shows the secondary structural elements and other features typical of all phage MCP that have the HK97 fold as a structural core. Blue features are present in all known structures, yellow features are present in some conformations but not others, and pink features are present in some phage species but not others. Features are named according to the type of secondary structure present if any, the domain in which they occur, and a number to differentiate similar elements. Number values are smaller for features that are present in more known structures. For example, the wedge-shaped A domain is composed of the five-stranded β sheet β B1, flanked by α A1 on the left and α A2 on the right. The position and conformation of α A2 varies more over different states and species than does α A1, while α A3 only exists in some states of some phages.

fold is divided into four domains: a wedge-shaped A-domain, a plank-shaped P-domain, an extended E-loop, and an N-terminal arm. All four domains change their structures as needed to meet the requirements of quasi-equivalence and maturational transformation. However, the A- and P-domains that make up the bulk of the shell of the capsid are less conformationally variable than the E-loop and N-arm which form bridges to bind neighboring MCP monomers together. Fig. 2 illustrates the HK97 fold and its conserved features and serves as a reference to the MCP features described below.

Major Capsid Protein Before Capsid Assembly

The structure of the prohead is a consequence of its ability to self-assemble from MCP in solution in the cytoplasm of host cells. As such, it is useful to understand the structure of tailed phage MCP before it has polymerized into a prohead as well as the evolutionary pressures that have dictated its structural properties. The canonical HK97 fold of the MCP appears to be incapable of folding properly on its own, as it precipitates out in random aggregates. This is not surprising; like any protein capable of self-polymerizing, MCPs are in danger of misfolding. Phage MCP sequences must encode complementary stretches of residues that can bind tightly to their intended partner in another monomer to form a robust capsid. However, these stretches could also lead to mis-folding if binding occurs intra- rather than inter-molecularly. HK97 itself avoids aggregation and assembles proheads only in the presence of the host GroEL/ES molecular chaperone system, as do lambda and other phages of *E. coli*. T4 codes for a particularly large MCP (521 AA), which is too large to utilize the host GroEL/ES system and thus encodes its own more capacious co-chaperonin analogous to GroES. In P22 and related phage, assembly-competent folding is provided without the apparent need for host factors by the addition of an “insertion” I-domain that folds rapidly and nucleates folding in the rest of the MCP. Point mutations in the I-domain lead to MCP aggregation and precipitation, presumably due to misfolding of the domain and thus the protein as a whole. P22’s I-domain is similar to the IG-like protein telokin. Other phages also include IG-like domains in their MCPs, but a role for these in promoting proper folding has yet to be demonstrated. However, proper folding requires more than just avoiding aggregation; initial inter-molecular interactions must be relatively weak so that MCPs in the prohead can freely dissociate and re-associate to find the lowest-energy arrangement of MCP subunits. This means that the MCP folds such that the stretches of polypeptide that bind strongly to each other in the final assembled structure are inaccessible until transformation into the mature head begins.

There is likely a soluble intermediate state of the MCP after it has folded but before it has assembled into a prohead. However, that intermediate, i.e., its conformation and oligomerization state, remains unknown for any phage. In HK97, pentamers and hexamers appear to be the soluble units. This is important because MCP is arranged in the finished capsid as pentamers and hexamers, collectively termed capsomers. It seems logical for the capsid to be constructed from pre-assembled capsomers, but this appears to not always be the case. Investigations into P22 assembly indicate that its prohead forms monomer-by-monomer, and non-denaturing gel electrophoresis studies in T7 suggest that MCPs are present as tetramers prior to prohead assembly. Clearly, more definitive biochemical, biophysical, and structural characterization of these intermediate species would significantly illuminate the mechanism underlying capsid assembly.

Prohead Assembly

Assembly of an icosahedral prohead with a Triangularization number (T number) greater than one requires MCP to adopt different conformations and bind together in different ways according to the quasi-equivalent positions of the lattice. However, this capacity for different conformations and binding also allows MCP to link together in a large number of incorrect arrangements

Fig. 3 Local Rules and Prohead Assembly. Two examples of ‘local-rules’ and their resulting assemblies are shown. On the top, monomer pair interactions that are more thermodynamically favorable are in a green box while pairs that do not quite fit together have less favorable interactions and are in the red box. These pairs with different interaction energies can be thought of as ‘rules’ which only allow interactions with more negative free energies of formation. The result of continuously adding monomers in compliance with the rules in the green and red boxes is a $T = 3$ icosahedron. A $T = 7$ icosahedron can be specified by a much larger set of rules, as shown in the lower half of the figure.

in addition to the correct one. Two levels of regulation are utilized to promote the assembly of the single MCP arrangement that yields functional proheads. In the first, termed ‘local rules’, interaction between MCP monomers is favored for specific pairs of different conformations and disfavored for others, as shown in Fig. 3. These rules may be satisfied by monomers with consistent conformations sampling many potential binding sites until one matches or they may move to binding sites randomly and switch conformations to match. The second level of regulation requires the participation of an additional protein known as the scaffold, which is encoded by all known tailed phages. As their name suggests, scaffolding proteins are necessary for proper prohead assembly but are not present in the mature phage. The scaffolding proteins act to protect against errors that would accumulate into fatal defects in an assembly process driven entirely by ‘local-rules’ MCP interactions. The combination of specific binding relationships dictated by the local rules of MCP and more global dynamic interactions of the scaffold ensures correct assembly of the prohead. Point mutations in either component can shift the equilibrium toward more misformed, nonfunctional proheads relative to the correct form.

Scaffolding Protein

The function of scaffolding proteins varies somewhat from phage to phage and has not been determined in full for any species. It has been investigated via *in vivo* studies of scaffold-deletion mutants and *in vitro* assembly experiments in which the scaffold was not included at all, or was included only as a truncated version. These experiments produce a wide range of phenotypes. T7 MCP produces no structures at all without scaffold, and the MCP remains in solution. The prolate phages T4 and phi29, in which

wild-type (WT) capsids consist of both icosahedral and cylindrical regions, produce elongated cylindrical and icosahedral-only structures, respectively. Long cylindrical “polyheads” are also produced by lambda, although its WT capsid is not prolate and thus has no cylindrical regions. P22 deletion mutants are able to produce some complete proheads, although at a greatly reduced yield and rate compared to WT. P2 MCP precipitates as random aggregates when scaffold is not present, as does HK97 MCP mutants from which the scaffold domain has been deleted. These different phenotypes suggest that scaffolding proteins perform several different functions, and the importance of each function varies among different phages. Some functions of scaffolding proteins that have been proposed include: (1) accelerating assembly, (2) promoting the correct overall curvature and shape of the prohead, (3) occupying the interior volume of the prohead to prevent host molecules from being trapped inside, (4) stabilizing MCP in its prohead conformation to prevent premature maturation, and (5) incorporating the portal protein at the unique vertex.

Accelerating assembly

Wild-type scaffolding-protein's accelerating function during prohead assembly is demonstrated by the observed slower assembly time of P22 MCP when scaffolding is absent. The mechanism of acceleration has been proposed to result from scaffold-bound MCPs being brought into close proximity via inherent oligomerization interactions of the scaffold. Specifically, scaffolding protein sequences in all phages have long stretches of sequence that promote alpha-helix formation and coiled-coil interactions. Indeed, the only two scaffolding proteins whose structures have been determined both form dimeric coiled-coils. Hence, if each monomer in a multimer can also bind MCP, then the inherent oligomerization of scaffold would bring MCPs into close proximity, increasing the local concentration and thus accelerating binding interactions. Experiments with truncated P22 scaffolding proteins show that acceleration of assembly occurs if and only if the region that promotes dimerization is present. In addition to the highly structured coiled-coil regions, most scaffolds also code for C-terminal regions of unstructured polypeptide. These partially unfolded regions would permit the polypeptide to sample a larger region of space, increasing the chance of finding its binding partners.

Promote correct geometry

In addition to the coiled-coil driven dimerization described above, the only crystal structures of scaffolding proteins indicate that two dimers associate to form tetramers. While, the mechanisms by which scaffolding protein promote correct assembly are not fully known, they may depend on this ability to form higher order oligomers. As described above, P22 MCP in the presence of mutant scaffold in which the dimerization region was deleted not only assembled proheads with much less accuracy than when WT scaffold was present, but also at a decreased assembly rate. In contrast, a scaffold mutant missing the putative tetramer-promoting region accelerated polymerization of MCP relative to WT scaffold, but produced a greater number of aberrant particles. In many phages, the most commonly seen aberrant particle is a ‘spiral’ which can be imagined as a particle wherein the curvature of the shell is not correct, and two leading edges have continued to grow past each other after failing to close. This defect illustrates the inadequacy of relying on local MCP/MCP interactions to define the geometry of the large number of subunits in the prohead; even small errors in local curvature can lead to a fatal misalignment when added over 360° . The larger volumes sampled by the scaffolding protein could bridge misaligned fronts and prevent larger-scale defects like the spiral shells (Fig. 4). By assuming this error correction function, the scaffold likely allowed the MCP more freedom to evolve, resulting in the wide range of observed capsid forms and likely contributing to the evolutionary success of tailed phages.

Fig. 4 The Role of the Scaffolding Protein in Correcting Errors During Prohead Assembly. Schematics of a commonly seen ‘spiral’ aberrant particle (left) and a closed prohead, assembled correctly with the aid of scaffolding protein (right) are pictured. As subunits are added to the growing assembly, differences in the curvature of the shell lead to two fronts failing to join and overlapping. The local interactions between MCP monomers cannot ‘detect’ the mismatch. Scaffolding protein monomers explore a large volume of space, so as the growth fronts approach each other they are brought into alignment by dimerization and tetramerization reactions. Proper joining is ensured and a high yield of closed shells results.

Delay MCP transformation

MCP monomers in partially assembled proheads must not transition to their tight-binding mature conformation before the subunits have assembled a closed shell with the thermodynamically favored arrangement. Scaffolding protein interactions with the N-arm of the MCP are involved in preventing premature expansion. In HK97-like phages, scaffold and major capsid protein are initially translated as a single polypeptide where the approximately 100 N-terminal amino acids correspond to scaffold and the rest of the protein to MCP. In phage that have this covalently attached scaffold (δ -domain), it must be proteolytically cleaved before maturation can occur, thus providing a mechanism to control the timing of scaffold departure. In phages that employ a separate scaffolding protein, maturation does not occur until negatively charged DNA and its counter-ions enter the prohead. High salt concentrations have been found to reduce or completely prevent binding of scaffolding protein to MCP; similarly, DNA entry may disrupt critical electrostatic interactions between MCP and scaffold.

Experimentally determined estimates of the stoichiometric ratios of scaffold to MCP in proheads are imprecise but are less than one in all cases where the scaffold is not a covalently-bound δ -domain. This implies that either not all MCP monomers are directly affected by scaffolding interactions or that the scaffold dynamically dissociates and associates with different MCPs to affect the entire prohead. If the latter, the scaffold must rebind after unbinding from an MCP monomer significantly faster than the monomer transforms to its mature state when unbound.

Exclude host factors

Crowding out host cellular components from the prohead interior is necessary to reserve the full volume of the capsid for storage of nucleic acid. A loss of volume to contaminants would prevent complete packaging of the phage genome, with an accompanying loss of infectivity. Scaffolding protein could prevent this scenario by simply occupying space inside the prohead. In experiments that reduce the length of a scaffolding protein, larger copy numbers compensate in the resulting proheads, resulting in a similar final scaffold-to-MCP mass fraction. Of course, scaffolding protein must also be able to exit the complete prohead to make room for the phage genome. Some phages have holes in their proheads' capsomers and their scaffolding proteins exit intact and can participate in assembling new proheads, while other phages co-assemble a protease inside the prohead which digests the scaffold which then exits as smaller fragments. In some cases, the scaffold itself provides the proteolytic function.

Scaffold involvement in portal incorporation

Inclusion of the portal into proheads assembled *in vitro* has been demonstrated to be promoted by the presence of scaffolding protein for many phages. Density near the portal in asymmetric cryo-EM maps of proheads has been attributed to scaffolding protein in HSV-1 and others. Mutations in the scaffolding protein of P22 have resulted in *in vitro* assembly of prohead particles that did not incorporate the portal. However, the mechanisms by which scaffolding proteins and portals interact has not been explored as thoroughly as the interactions that promote MCP assembly into the prohead.

All these functions depend on the scaffold's ability to bind phage MCP and to self-associate in a manner that promotes a particular internal volume. In phages where structural or mutagenic information is available, MCP binding typically involves a helix-turn-helix motif approximately 100 amino acids from C-terminal of the scaffolding protein binding via non-covalent interactions to the N-arm of the MCP. The fact that scaffolding proteins seem to immediately precede MCP in the phage genome suggests an evolutionary relationship between the N-terminal delta-domain of some phages and the separate but sequence-adjacent scaffolding proteins of others. Either the scaffolding protein and MCP genes fused in HK97 and some other phages, or the combined protein is ancestral and split into the two separate genes we now find in most phages.

The Portal

In addition to the MCP and the SP, viable proheads must include a portal protein. This protein assembles into a dodecameric funnel-shaped 'portal' structure, sometimes also referred to as the connector since it will 'connect' the head to the tail in the mature phage. The portal occupies the unique vertex of the icosahedral capsid and provides the pore through which DNA can enter and exit the phage during genome packaging and ejection, respectively. The outermost narrow-end of the funnel-shaped portal interacts with the DNA-packaging ATPase motor in the prohead and with the tail in the mature virion. It has been hypothesized that the wide-end of the portal funnel, which is located in the interior of the prohead, senses DNA filling and initiates an allosteric conformational change that (1) causes the motor to detach at the end of genome packaging and (2) constricts the central channel of the portal such that DNA will be blocked from exiting the prohead until the tail can bind and serve as a plug to prevent premature DNA ejection. The portal is therefore important for maturation. Proheads of T4 showed delayed expansion when the portal protein was modified. The portal also has an important role in prohead assembly, though the details are not consistent for all species of phage. In T4, phi29, HSV1, and T7 the portal has been shown to be necessary for assembly of MCP into capsids with the correct geometry, and is proposed to serve as nucleation site for procapsid assembly. This hypothesis is attractive since it provides a simple explanation as to why only a single portal is incorporated in the prohead structure. However, early experiments in phage P22 suggested that portal incorporation occurs as the last step of prohead assembly rather than the first. Specifically, *in vitro* assembly of icosahedral P22 shells can proceed from MCP and scaffolding protein alone, while inclusion of an excess of portal protein results in aberrant spiral particles with multiple portals incorporated. However, recent studies indicate that P22 assembly proceeds similarly to other phages, with the portal nucleating assembly. The structure of the portal itself suggests it must

be incorporated early in prohead assembly since the radius of the wide end of the funnel-structure of the portal is positioned in the prohead interior and is wider than the hole where the portal sits. Hence, it is difficult to imagine how this wide funnel-end of the portal could pass through this hole if it were incorporated into proheads as the last step in assembly.

Structure of the Prohead

The prohead's structure differs from that of the mature head in its overall shape and size, in the local arrangement of monomers, and in the conformation of the individual monomers themselves (Fig. 5). Compared to the mature head, the prohead is smaller in diameter, has rougher and thicker capsid walls, and more closely resembles a sphere than an angular icosahedron. The spherical shape of the prohead suggests that while the MCP monomers interact quasi-equivalently, the scaffolding proteins' dynamic oligomerization interactions are equivalent and not sensitive to different positions in the icosahedral shell. The capsomers are cup-shaped as opposed to the flat capsomers in mature heads, which is what causes the prohead shell to have a rougher appearance. Cup-shaped capsomers result in shorter distances across capsomers and therefore smaller prohead diameters and internal volumes. The previously described functions of scaffolding proteins can be achieved more easily with a smaller internal volume. The magnitude of expansion varies significantly among phages (e.g., a 100% increase in diameter for phage lambda versus a 30% change for P22). Capsomers in proheads also tend to have lower symmetry, as typified by the skewed, two-fold symmetric hexons in $T = 7$ icosahedral phage which transition into nearly six-fold symmetry during maturation. Reduced symmetry in prohead capsomers increases the ability of 'local rules' to regulate assembly since the energy difference between 'correct' and 'incorrect' hexamer/hexamer interactions will be greater. Many phages encode accessory proteins that bind to the mature capsid and provide further stabilization. For example, hoc and soc in T4, and gpD in lambda stabilize the mature head to the extent that maturation is an essentially irreversible event. These proteins are unable to bind to the MCP in the prohead state, and the detection of their binding has been used to assay prohead maturation. The differences between the prohead and mature capsids are illustrated in Fig. 5, using phage HK97, as a representative of tailed dsDNA phage generally.

All of the differences in size and shape between proheads and mature capsids are the result of conformational transitions in all the individual MCPs. These transformations are complex, and to simplify their description, we focus on the changes that occur at different inter-monomer junctions, categorized based on the number and parts of capsomers involved. We will examine the

Fig. 5 Transformation from Prohead to Mature Head. The transformation of the HK97 prohead into a mature head is shown at several scales. In A and F, the entire capsid changes from a small bumpy spheroid into a larger, smoother icosahedron. In B and G, density simulated from atomic coordinates of the $T = 7$ asymmetric unit includes an entire hexon, which changes from a 2-fold symmetric skewed form into a more 6-fold symmetric hexagon. C and H show cross-sections of the hexons in which the change from a cup-shape to a more flat shape can be observed. D and I show ribbon diagrams of the atomic models of the asymmetric unit. In E and J, each monomer in the asymmetric unit has been superimposed for each state, showing the greater variability of the monomers in the prohead, especially at the tips of the A-domain and the P-domain.

conformational changes that occur upon maturation at (1) capsomer vertices where three MCPs meet, (2) across capsomer edges where two MCPs interact, and (3) at capsomer centers. In addition to the structural rearrangements at monomer-monomer interfaces, we will also describe that changes in the basic fold of the MCP that accompany maturation, (Fig. 6). Note that only five high-resolution prohead structures have been published at the time of this writing, so we should be cautious in drawing conclusions; features common to these structures may not be present in all subsequent structures.

The interfaces where three capsomers meet at their vertices remain largely the same before and after maturation. In most phages, the P-loops of three monomers contact each other, and these contacts do not change during maturation. MCPs at the five- or six-fold symmetry axis at the center of a capsomer undergo significant refolding and rearrangements during maturation, and this seems to drive the transition from skewed 2-fold hexamers to the more symmetric 6-fold state observed in mature capsids. In the prohead state, the interactions between neighboring monomers at the centers of capsomers mostly involve helices α 1 and α 2. When skewed prohead hexons mature into the more 6-fold symmetric state, this is accompanied by an increase in the length of α 1 and, in some of the monomers, movement of α 1 results in a different set of interactions with α 2. The most substantial structural changes occur at the interfaces joining the edges of two capsomers, resulting in entirely different interaction networks. These maturation changes are consistent in all available prohead/mature head structure pairs, and likely drive the transition from prohead to expanded mature head.

As discussed above, changes at the twofold interface during maturation are the most extensive and give rise to a completely different set of paired interactions. Most of these changes result from movement and refolding of the N-arm, which is uninvolved in the prohead 2-fold interface but prominently involved in the interface in the mature head state. The change in binding is most obvious at the position of the local twofold axis halfway along the interface. In the mature state neighboring N-arm strands cross each other, while in the prohead the 'N-shoulders' of opposite monomers meet. The term 'N-shoulder' refers to the loop connecting the lower strand of the E-loop to the bottom strand of β P2 which leads directly to the N-arm (Fig. 2). The thermophilic archaeal phage P23-45 is an exception in that the tips of the long spine helices meet at the 2-fold axes rather than the N-shoulders.

Fig. 6 Inter-MCP interfaces before and after maturation. Conformational changes in the HK97-fold during the prohead/mature head transformation are categorized by their participation in different interfaces in the capsid. Threefold junctions, where the corners of three capsomers meet, remain mostly unchanged. Twofold junctions, where the edges of two capsomers meet, undergo significant unbinding, movement, refolding, and rebinding. Junctions at the centers of capsomers undergo some refolding in all monomers. In skewed hexons, α 1 of some monomers unbind from their prior locations and rebind in positions that match those of the other monomers.

The capsomers of P23–45 (and P74–26) are much larger than those of all known mesophilic phages (~ 170 versus ~ 120 – 140 Å from capsomer center to capsomer center), which is the result of large additions and extensions to the canonical HK97 fold. Features are thus shifted into a different alignment. Despite this, the same overall logic prevails at the twofold interface, with different pairs of features binding across the interface in the prohead and mature state. Non-conserved features that supplement binding across the prohead 2-fold interface are present in most phages. Prominent examples are the G-loop in HK97 and the D-loop of the I-domain in P22. In these cases, the complementary binding site is on the outer strand of $\beta E1$ and $\beta P1$. This complementary site is closely associated with a short helix on the N-arm in the mature head state. In summary, despite differences in the details, it seems that all interactions which stabilize the two-fold interfaces of the prohead are disrupted by the N-arm at some point during maturation. The residue pairs that interact in the prohead state are in proximity with one another when the monomers are in their more convex shape, and farther apart after capsomers have flattened out in the mature state. This change in curvature is especially pronounced in the long ‘spine’ helix of the P-domain. In proheads, a second helix formed by the N-arm lies alongside the spine helix and seems to stabilize its greater curvature. Hence the N-arm is important for both stabilizing the prohead state during assembly and destabilizing it during maturation.

Stability of the Prohead

Proheads are metastable, that is, they are not in the lowest possible thermodynamic state, but the rate at which they transition to the more thermodynamically favored mature state is slow enough that they are ‘stable’ in the conversational sense of the word. The MCP in assembled proheads is in dynamic equilibrium with subunits in the solution phase. Indeed, purified proheads of P22 have been shown to partially disassemble if diluted below their dissociation constant of $5\text{ }\mu\text{M}$. Proheads of several phage have also been found to expand spontaneously (i.e., before the scaffold δ -domain has been cleaved or DNA has been packaged) under certain environmental conditions. Elevated temperature, or the addition of 4 M urea or surfactant can trigger this process. In P22 and HK97, manipulation of the environment has produced ‘wiffle-ball’ capsids, which have all their hexons present and in the flattened expanded state, but which have lost their pentons leaving large holes that give the resulting particle the appearance of a wiffle ball. This may be due to the scaffold remaining bound to the N-arms such that the N-arms from pentameric MCPs are unable to stabilize the 2-fold interfaces as in fully matured capsids. As a result pentameric capsomers are bound too weakly to remain attached to the capsid and dissociate. In Phi-29, structures of partially matured capsids have been determined where there are large gaps between the edges of pentamers and adjacent hexamers. In these particles, scaffold remains attached to the N-arms of pentons after hexons have matured, resulting in weakly bound pentamers with very few contacts joining them to neighboring hexamers. Both these particles and the HK97 wiffle balls likely represent particles where hexamers transitioned to the mature state but pentamers did not.

Assembly Parasites

Scaffold-assisted assembly of a prohead followed by maturation has been an enormously successful assembly strategy for tailed phages, as evidenced by their prevalence throughout the biosphere. However, this strategy has a drawback in that it allows parasitism by virophages that encode scaffold proteins that can compete for another phage’s MCP. The *Staph. aureus* Pathogenicity Island (SAPI) and *E. coli* satellite phage P4 both encode a scaffolding protein that induces the MCP of another ‘helper’ phage to form smaller capsids that cannot contain the genome of the helper phage and preferentially package the virophage genome. In the case of SAPI, the scaffolding protein is internal and analogous to those encoded by the helper phage, 80- α , but has a higher affinity for the 80- α MCP and outcompetes the 80- α helper scaffold for MCP binding, leading to smaller $T = 4$ capsids rather than the $T = 7$ of WT 80- α . Another SAPI-encoded protein may block MCP/helper scaffold binding by binding the helix-turn-helix region of the scaffold that binds to MCP. P4 encodes an external scaffold, sid, which directs the P2 MCP into $T = 4$ capsids and can do so when the helper phage’s internal scaffold is not present. Given the high degree of gene exchange between host cells, viruses, and virophage, we might expect to eventually find HK97-like phages that use an external scaffold similar to P4’s sid for capsid size determination instead of the ‘traditional’ internal scaffold protein.

Glossary

AXP Denotes an ATP/ADP binding site.

bZIP Conserved basic leucine zipper DNA-binding motif.

IHF The *Escherichia coli* integration host factor protein.

NTP Denotes an ATP/ADP and GTP/GDP binding site.

TerL The large terminase subunit.

Terminase holoenzyme The heterooligomeric, catalytically competent terminase enzyme complex composed of TerL and TerS subunits.

Terminase protomer The stable, protomeric TerL•TerS₂ heterotrimer of phage λ terminase.

TerS The small terminase subunit.

WA Conserved Walker A ATPase motif.

WB Conserved Walker B ATPase motif.

wHTH Winged helix-turn-helix DNA binding motif.

Introduction

Viruses are obligate intracellular parasites whose developmental pathways are initiated upon insertion of their genetic material into a host cell. Subsequently, viral genomes and structural proteins are synthesized and infectious particles are assembled utilizing a number of viral and host-encoded biomolecules. The assembly pathways follow sequential steps generating transient intermediates that transition to the next, typically in a non-reversible manner. The pathways are generally conserved within broad virus classes such as the large dsDNA viruses, which includes the *Caudovirales* (tailed bacteriophages) and the *Herpesviridae* groups. In these cases, viral DNA is typically replicated via a rolling circle mechanism resulting in linear, head-to-tail concatemers of the viral genome (*immature DNA*). Expression of late viral genes produces structural proteins that self-assemble into procapsid shells into which the newly replicated DNA is actively packaged. *Genome-packaging* represents the intersection between the DNA replication and capsid assembly pathways and involves processive excision of a single genomes from the concatemer and simultaneous packaging of the “mature” DNA into a preassembled procapsid shell; both reactions are catalyzed by a virus-encoded *terminase enzyme*.

Genome packaging pathways are strongly conserved in the dsDNA viruses and can be summarized as outlined in [Fig. 1](#); the terminase enzymes assemble at a specific packaging initiation site in the genome concatemer (*pac* or *cos*) to afford a stable, site-specifically bound *maturation complex*. This activates an endonuclease activity that cuts (matures) the duplex to generate the first end of the genome to be packaged. The post-cleavage complex binds to a portal situated at a unique vertex of a pre-assembled procapsid; the portal is a ring-like structure that provides a conduit for DNA entry into the capsid during packaging and for exit during infection. Terminase binding to the portal affords the *packaging motor complex*, which triggers a transition from a stable, site-specifically bound maturation complex to a dynamic motor that translocates DNA into the shell in a sequence-independent manner, fueled by ATP hydrolysis.

Terminase motors are extremely processive and very powerful; they package the entire genome length in a single binding event and to liquid crystalline density, which generates a remarkable > 25 atmospheres of internal shell pressure. Upon packaging a genome-length of DNA, the enzyme transitions back to a static maturation complex that again cuts the duplex to terminate the packaging process (from which the enzymes derive their name). The binary terminase•DNA complex, formally equivalent to the maturation complex that initiated packaging, is displaced from the genome-filled capsid by “finishing” proteins and binds another empty procapsid to initiate a second round of processive genome packaging ([Fig. 1](#)). Addition of a pre-assembled tail to the nucleocapsid (*Caudovirales*) or a complex lipid envelopment process (*Herpesviridae*) ultimately affords an infectious virus.

The essential features described above are strongly conserved in the large dsDNA viruses, both prokaryotic and eukaryotic, and the terminase enzymes perform two essential functions in virus assembly; (1) nucleolytic excision of individual genomes from a concatemeric precursor (*maturation reaction*) and (2) translocation of viral DNA into the procapsid (*packaging reaction*). These two reactions are catalyzed by two distinct terminase complexes that sequentially alternate during processive genome packaging. Notable exceptions to this general paradigm are represented by the phage $\phi 29$ and adenovirus groups, which replicate monomeric genomes in a protein-primed manner and thus have no maturation requirement. Notwithstanding, these viruses utilize an analogous “packaging ATPase” enzyme to package viral DNA into a pre-assembled procapsid shell. Herein I focus on the enzymology of the dsDNA viruses that package genomes from a concatemeric DNA precursor, which include phages λ , HK97, T4, P74-26, P22 and SPP1, among others, and the eukaryotic herpesviruses.

Unit Length Versus Headful Packaging Mechanisms

Within the broad class of dsDNA viruses, terminases carry out two basic strategies for genome packaging. The “unit-length” phages both initiate and terminate packaging at a “*cos*” sequence and thus package exactly 100% genome length ([Fig. 1](#)); the herpesviruses

Fig. 1 Processive genome packaging in the dsDNA viruses. Terminase enzymes are responsible for processive excision of an individual genome from a concatemeric packaging substrate (*genome maturation*) and for translocation of the duplex into a pre-formed procapsid shell (*genome packaging*). The functional enzymes are composed of large catalytic (*TerL*) and small DNA recognition (*TerS*) subunits, both of which possess conserved functional domains, as depicted at bottom, left. Two basic strategies for genome packaging, unit-length and headful, are summarized at bottom, right. Processive packaging requires that terminase cycles between a stable maturation complex and a dynamic motor complex. Details are provided in the text.

similarly initiate and terminate packaging at repeated “a” sequences in the concatemer. In contrast, while the “headful phages” initiate packaging at a “*pac*” sequence, the translocating motors bypass the downstream *pac* site and continue packaging until a “head full” of DNA has been inserted into the shell. This affords virions that contain DNA 104%–110% larger than the unit-length genomes and that possess “circularly permuted, terminally-redundant” ends (Fig. 1). In both cases, processive genome packaging from the concatemer requires that the terminase enzymes catalyze both genome maturation and DNA translocation reactions, alternating between distinct, but tightly coupled nucleoprotein complexes.

The Viral Terminase Enzymes

Terminase enzymes function as heterooligomeric complexes consisting of a large catalytic subunit that contains both maturation and packaging activities (*TerL*) and a small DNA recognition subunit that is required for site-specific assembly at the packaging initiation site (*TerS*; Fig. 1); both subunits are essential for virus development *in vivo*. In some cases, such as phages λ and P22, the holoenzymes can be isolated as stable complexes of both subunits, while in others, such as phages T4 and SPP1, the two subunits do not strongly interact until they assemble the maturation complex on DNA.

The *TerS* Subunits

The small DNA-recognition subunits (~17–23 kDa) are generally composed of conserved functional domains (see Fig. 1); (1) an N-terminal DNA binding domain containing a helix-turn-helix DNA binding motif, (2) a highly helical central self-association domain and (iii) a C-terminal domain that also plays a role in DNA binding and that is required for binding to the *TerL* subunit in the holoenzyme. The isolated *TerS* subunits assemble into ring-like structures ranging from 8 to 11 subunits of varying dimensions, and in some cases double rings. Due to this structural diversity, there is debate as to whether *TerS* binding to DNA threads the duplex through the central channel of the rings or if it wraps the duplex around the perimeter of the rings. This is discussed further below.

The *TerL* Subunits

The large catalytic subunits (~50–80 kDa) are typically monomers in solution whose overall fold is conserved despite their divergent primary sequence; they are similarly composed of conserved domains (see Fig. 1). An N-terminal domain contains the packaging ATPase site that fuels motor movement; sequence, structural and biochemical data suggest that the packaging ATPase belongs to the Additional Strand, Conserved Glutamate (ASCE) family of ATPase enzymes. As such, they possess the conserved Walker A (WA) and Walker B (WB) motifs that participate in ATP binding and positioning the γ -phosphate for hydrolysis. A conserved “catalytic glutamate” lies immediately downstream of the classical WB motif and is proposed to position and activate a water molecule for nucleophilic attack on the γ -phosphate in the hydrolysis transition state. The terminase family also possess a *trans*-acting “arginine finger” residue that is conserved in ring ATPase enzymes; these residues are proposed to (1) catalyze ATP hydrolysis in an adjacent subunit and (2) to communicate the nucleotide bound state of one subunit in the motor to the next. These features serve to ensure inter-subunit communication and coordination of ATP hydrolytic events during motor movement. Finally, a “lid” domain is also conserved in the terminase enzymes that is likely involved in coupling ATP hydrolysis to duplex movement.

A short linker connects the packaging ATPase domain to a conserved C-terminal nuclease domain responsible for genome maturation. Structural interrogation suggest that the nuclease domains are related to the RNaseH family of nuclease enzymes. Non-specific nuclease activity has been demonstrated in several headful TerL subunits and their nuclease domains, including phages T4, SPP1 and P74-26, among others, and the nuclease domain of herpes simplex and cytomegaloviruses. Biochemical and kinetic characterization of nuclease activity of these proteins has generally been modest; nevertheless, similar features are apparent in both prokaryotic and eukaryotic systems, as follows. Duplex nicking requires divalent metal and structural studies suggest a two-metal nuclease mechanism. Nuclease activity is non-specific, it is often weak and where examined, it is inhibited by the TerS subunit. Kinetic analysis of the nuclease activity of P74-26 TerL indicates that the enzyme possesses both single-strand nicking and double-strand duplex cleavage activities.

In contrast to the headful phages discussed above, the nuclease activity of unit-length genome packaging terminases, such as those from phages λ , 21 and HK97, is site specific and strictly requires the TerS subunit. This is described in detail below.

The Terminase Holoenzymes

Genetic and biochemical data indicate that holoenzyme complexes composed of both TerL and TerS subunits are required to assemble the maturation complex at *pac* or *cos* to initiate genome packaging. Where characterized, C-terminal residues in the TerS subunits are required for binding to N-terminal residues in TerL to assemble functional holoenzymes. Unfortunately, structural studies performed to date have characterized the TerL and TerS subunits in isolation and while they have provided significant insight into structure-function relationships of the isolated terminase subunits, there is little information on the holoenzyme complexes assembled from both subunits. Elegant single molecule tweezer studies have revealed mechanistic details of DNA translocation by the translocating motors, again most often in the absence of the cognate TerS subunit. Moreover, there is limited information regarding the conserved genome *maturation* complexes and a mechanistic interrogation of the tightly coupled maturation and packaging catalytic activities remains largely unexplored. An exception is phage λ terminase, which is isolated as a stable heterotrimer of TerL and TerS subunits and has been extensively studied genetically, biochemically and by single-molecule techniques.

This article focuses on the enzymology of phage λ terminase as a model system for interrogating the conserved nucleoprotein complexes that catalyze genome maturation, that drive DNA translocation and the cyclic interconversion between the two required for processive genome packaging. Biochemical and kinetic characterization of λ terminase has revealed complex allosteric interactions between the nucleotide and DNA binding sites that bear directly on these conserved transitions. While the focus will be on λ , comparisons to other viral systems are discussed in order to provide a broad discussion of the enzymology and biochemical features of virus DNA packaging.

The Lambda System

Bacteriophage λ is composed of a linear 48.5 kb dsDNA genome tightly packaged within an icosahedral capsid shell that contains a tail structure situated at a unique vertex of the icosahedron (the portal vertex). Injection of viral DNA into an *Escherichia coli* cell initiates the infection cycle, which ultimately affords linear concatemers of the λ genome and packaging-competent procapsids. Phage λ assembly has been fully reconstituted *in vitro* and an infectious virus may be assembled using purified proteins and commercially available λ DNA; this allows mechanistic interrogation of each step along the virus assembly pathway.

The Terminase Enzyme of Phage Lambda

λ terminase purifies as a stable, homogeneous heterotrimer composed of two TerS subunits tightly associated with a single TerL subunit [TerL•TerS₂, the *terminase protomer*]. The two subunits possess the conserved functional domain organization described above and a number of structural motifs and catalytic sites have been characterized in each subunit. The protomer is catalytically silent and is activated only when assembled into a higher-order ring-like *holoenzyme complex*. Detailed biochemical interrogation of the enzyme has revealed complex allosteric interactions between the multiple substrate binding and catalytic sites identified in the enzyme, as outlined in Fig. 2.

The λ TerS Subunit

Genetic, biochemical and structural studies identified an N-terminal DNA binding domain (DBD) in λ TerS that contains a winged helix-turn-helix (*wHTH*) motif and that assembles into a stable dimer. Based on structural modeling data, we proposed that the HTH motif interacts with the major groove of DNA and that the wing acts as a nucleotide modulated switch that regulates *cos*-specific versus non-specific DNA binding interactions that are important for maturation and translocation activities, respectively. Consistent with this model, a low-affinity nucleotide binding site has also been identified in this domain, which binds both ATP/ADP and GTP/GDP nucleotides (NXP, $K_{D,app} \sim 0.5\text{--}1\text{ mM}$). While early studies reported ATP/GTP hydrolysis at this site, more recent studies with the purified and homogenous protomer suggest that turnover at this site is very low. Rather, this nucleotide binding site appears to act as an allosteric regulator of terminase function; NXP binding to this site (1) modulates *cos*-specific versus non-specific DNA binding

Fig. 2 Domain organization and allosteric communication between the binding and catalytic sites in λ terminase holoenzyme. TerS and TerL are shown in cyan and blue, respectively. The TerS DNA binding domain contains a winged helix-turn-helix DNA binding motif (*wHTH*) and an allosteric NXP binding site (*NXP* denotes ATP/ADP or GTP/GDP). The TerL packaging ATPase and genome maturation domains are depicted, connected by a short linker domain. *AXP*, denotes ATP/ADP and *bZIP* denotes a basic leucine-zipper motif. Characterized allosteric interactions between the nucleotide, DNA and catalytic sites are indicated. Details are provided in the text.

interactions, (2) inhibits the nuclease activity of TerL and (3) stimulates ATP hydrolysis by the packaging ATPase site in TerL (Fig. 2). These features have been incorporated into a “nucleotide switch” model that is responsible for alternation between the maturation and packaging complexes during processive genome packaging (*vide infra*).

Following the DBD is a long (~ 100 residues) hydrophobic coiled-coil helix that plays an important role in TerS self-assembly interactions and that is likely involved in protomer and motor assembly. The helix connects to a C-terminal domain that similarly plays a role in higher-order self-association interactions, that is required for high-affinity DNA binding interactions and that is also responsible for binding to the TerL subunit in the λ protomer (**Fig. 2**). As noted above, the domain organization and structural features described for λ are generally conserved in all of the TerS subunits characterized thus far (*vide supra*).

The TerL DNA Packaging Domain

The genome packaging activity of λ terminase is located in an N-terminal domain of TerL that contains the highly conserved ASCE ATPase catalytic site described in detail above. Kinetic studies reveal that the λ domain binds ATP with high-affinity ($K_M = 5 \mu\text{M}$) and that turnover at this site is stimulated by NXP binding to the TerS subunit in the holoenzyme (see [Fig. 2](#)). Further, non-specific DNA duplexes stimulate ATP hydrolysis at this site, while binding to specific *cos*-containing DNA sequences inhibits ATPase activity. These features are likely involved in regulating terminase ATPase activity in the maturation versus motor complexes.

The λ TerL Maturation Domain

As a unit-length packaging enzyme, λ terminase introduces site specific nicks into the *cos* sequence 12 bases apart. This catalytic activity is contained within a C-terminal RNaseH-like nuclease domain of TerL that is conserved within the terminase family, as discussed above. In contrast to the TerL subunits of the headful phages, λ TerL does not possess non-specific nuclease activity. Moreover, site-specific cleavage at *cos* requires the TerS subunit and further assembly into a multimeric nuclease complex. A so-called “helicase” strand-separation activity is also centered in this domain which separates the nicked, annealed strands generated by the *cos*-cleavage reaction; the upstream D_R fragment is ejected from the complex and the D_L strand, which is to be packaged, remains tightly bound to the enzyme ($T_{1/2} \sim 8$ h).

A second high-affinity ATP/ADP (AXP) binding site is situated in the nuclease domain ($K_{D,app} \sim 1 \mu\text{M}$) and AXP binding to this site strongly stimulates both *cos*-cleavage and strand-separation activities of the enzyme (see Fig. 2). Turnover at this site is not observed and AXP appears to act solely as an allosteric effector of TerL maturation activity. It is noteworthy that ATP stimulates the non-specific nuclease activity of TerL subunits in the P22, Sf6 and P74-26 phage systems, but this has not been studied in detail. Further, a second ATP binding site, distinct from the packaging ATPase site was also proposed in the phage T4 TerL subunit based on sequence homology; however, genetic studies have not revealed a defined function for the putative site.

While the domain organization of λ terminase is strongly conserved among all of the terminase enzymes, catalytic variations exist. An interesting variation is the terminase enzyme from phage HK97, which also possesses a *cos*-specific nuclease activity that is dependent on TerL and TerS subunits; however, efficient duplex nicking further requires a nuclease-associated "HNH" protein, that appears to be common among the long-tailed phages. The mechanism by which this HNH protein stimulates the *cos*-cleavage

Fig. 3 Phage λ TerS and *E. coli* IHF cooperatively bind and bend *cos*-DNA. The λ *cos* sequence is bi-partite consisting of *cosB* terminase binding and *cosN* duplex nicking subsites. *cosN* possesses a pseudo-dyad symmetry and terminase introduces nicks into the duplex, 12 bases apart (red arrows). IHF binds to the *I1* element while a TerS dimer binds to the *R3* and *R2* elements, both of which introduce a strong bend in the duplex. Characterized thermodynamic binding constants are indicated and a structural model for the ternary IHF•TerS•*cosB* complex is shown. Similar binding constants are obtained with the λ terminase protomer [TerL•TerS₂] indicating that terminase assembly at *cos* is primarily mediated by the TerS subunit. The bent and likely wrapped duplex presumably positions a head-to-head TerL dimer symmetrically disposed at *cosN* as a catalytically competent duplex nicking complex. Structural details remain speculative at this time.

reaction remains obscure. Of note, the herpesviruses also appear to encode a three subunit terminase, but the correspondence between the prokaryotic and eukaryotic terminase subunits is unclear.

Escherichia Coli Integration Host Factor

IHF was first identified as a host protein required for λ lysogeny. This 20 kDa α/β heterodimer plays an important role in host DNA replication, transcription and site-specific recombination. IHF is also required for lytic λ development and strongly stimulates the genome maturation activities of λ terminase *in vitro*. In all characterized cases, IHF binds to a specific recognition element and introduces a strong bend in the DNA (160° – 180°); this provides a duplex architecture conducive to assembly of additional regulatory/catalytic proteins at that site.

The Genome Maturation Complex

The Lambda Cohesive End Site and Assembly of the Genome Maturation Complex

The λ *cos* sequence spans ~ 260 bp and is bi-partite consisting of a binding subsite (*cosB*) that is required for site maturation complex assembly and a nicking subsite (*cosN*) into which terminase introduces symmetric nicks in the duplex (Fig. 3). Genetic and biochemical data indicate that the isolated TerS subunit specifically binds to three repeating “R-elements” in *cosB* and similar to IHF, TerS binding introduces a strong bend in the duplex (160°). Cooperative binding and bending of *cos*-DNA by IHF and λ TerS has been demonstrated ($K_{D,app} = 22 \text{ nM}$, $\Delta\Delta G = 1 \text{ kcal/mol}$). A high-resolution NMR structure of the λ DNA-binding domain has provided insight into the molecular details of the IHF•TerS•*cosB* nucleoprotein complex, as depicted in Fig. 3; IHF binds to the *I1* element in *cosB*, bending the duplex and juxtaposing the *R3* and *R2* TerS binding elements. The wHTH motifs in the TerS DBD are presented on opposite sides of the dimer such that each can appropriately bind to an R-element in the bent duplex.

Ostensibly, the TerS•IHF•*cosB* bent duplex serves to appropriately position two TerL subunits symmetrically disposed at the *cosN* subsite to enable high-fidelity *cos*-cleavage activity (red arrows, Fig. 3). Similar to what is observed with the isolated TerS subunit, biophysical studies have demonstrated that the terminase protomer [TerL₁•TerS₂] and IHF also bind to *cos*-DNA with high affinity ($K_{D,app} = 20 \text{ nM}$) and cooperativity ($\Delta\Delta G = 1 \text{ kcal/mol}$). Comparison of the TerS and protomer thermodynamic binding data suggest

Fig. 4 Model for λ maturation complex assembly at *cos* and duplex nicking. Four λ terminase protomers and IHF cooperatively bind to the *cos* sequence to assemble a dimer of dimers nuclease complex and position a head-to-head TerL dimer symmetrically bound to the *cosN* subsite; the nucleoprotein complex strongly bends and wraps the duplex. Assembly down-regulates the packaging ATPase site and activates nuclease activity, which introduces symmetric nicks into *cosN*, 12 bases apart (red arrows).

that recognition and assembly of the terminase protomer at *cos* is primarily mediated by the TerS subunit. Consistent with these observations, while terminase and IHF cooperatively assemble at the *cos* sequence to engender a catalytically competent nuclease complex, the protomer alone does not discriminate between non-specific and *cos*-containing duplexes and is devoid of nuclease activity.

The physical nature of the duplex in the maturation complex is of interest. As discussed above, isolated TerS subunits and subdomains assemble into ring-like complexes with central channels of varying dimensions, which has led to a controversy as to whether DNA passes through the central channels or whether the complexes wrap the duplex around the TerS ring exterior; however, the role of TerS is to site-specifically assemble TerL into a catalytically-competent holoenzyme complex at *cos/pac*. Thus, interpretation of the structural data is complicated by the fact that (1) the TerS structures were obtained in the absence of the cognate TerL subunit and (2) they were all examined in the absence of DNA, both of which are required for the assembly of a biologically-relevant complex. It is further unclear whether the structurally characterized complexes are representative of TerS subunits assembled into a maturation complex or into the packaging motor complex. Thus, the duplex structure in the maturation complex remains speculative in all systems.

Model for the Assembly of the Genome Maturation Complex

The ensemble of structural, kinetic and biophysical data can be incorporated into a model for maturation complex assembly at *cos* and the activation of maturation activities in phage λ terminase, as depicted in Fig. 4. The terminase protomer, which is the relevant species during a productive infection *in vivo*, is essentially devoid of catalytic activity; however, the protomer and IHF at physiological concentrations cooperatively assemble at a *cos*-sequence of a genome concatemer to afford a catalytically-competent maturation complex. This provides a mechanism to avoid potentially damaging effects of non-specific nuclease; activity is activated only upon assembly at the packaging initiating site. Biophysical interrogation of the λ maturation complex suggests that four protomers and one IHF dimer assemble at the *cos* sequence to engender the catalytically competent ring-like nuclease complex [TerL₄•TerS₈•IHF] in which the duplex is highly bent and/or wrapped. Importantly, kinetic studies demonstrate that the packaging ATPase site in TerL is downregulated in the assembled maturation complex (see Fig. 2); this allosteric interaction serves to ensure a stable, site-specifically bound nucleoprotein complex and prevent pre-mature translocation from the *cos*-sequence.

Given the conservation of structure and function in the terminase enzymes, this model is likely recapitulated, albeit with some variation, in the terminase enzyme family. Consistent with this hypothesis, TerS-mediated duplex bending at the *pac* site has been demonstrated in the SPP1 system, among others. In contrast, the TerS subunits *inhibit* the nuclease activity and *stimulate* the ATPase activity of TerL in the T4, SPP1 and P22 headful phage systems *in vitro*. These observations appear contrary to the role of TerS in assembling a stable, site-specifically bound nuclease complex to initiate genome packaging and it is clear that further biochemical characterization of the headful terminase enzymes is necessary to clarify this discrepancy.

Genome Maturation: The *cos*-Cleavage Reaction

Once assembled at *cos*, λ terminase cuts the duplex within the *cosN* subsite. This site displays two-fold rotational symmetry and the nicks are symmetrically introduced into the upper and lower strands 12 bases apart (Fig. 4). Based on this symmetry and the presence of a basic leucine zipper (bZIP) DNA-binding/dimerization motif in the C-terminus of TerL (Fig. 2), it is not surprising that early models predicted that two TerL subunits are directly bound to the *cosN* half-sites, “head-to-head” in the maturation complex. This model bears analogy to the classical type II restriction endonuclease enzymes and similar head-to-head nuclease complexes have been proposed in the T4 and SPP1 systems; however, biophysical data suggest that the catalytically competent λ complex is composed of *four* terminase protomers. How can this be rationalized?

The *cos*-cleavage endonuclease reaction and the presumed stoichiometry of terminase protomers in the maturation complex is reminiscent of the Type IIE and Type IIF restriction endonucleases. In these enzymes, a dimeric head-to-head complex can assemble at a specific duplex nicking site, but this intermediate possesses weak nuclease activity. The catalytic activity of the dimer is strongly activated by direct association with a *second* DNA-bound dimer to yield a “dimer of dimers” nuclease complex through

Fig. 5 Model for symmetry resolution and motor assembly. The head-to-head dimer of dimers nuclease complex must re-orient the protomers to engender a parallel ring-like motor complex for binding to the portal vertex (*symmetry resolution*). TerL and TerS subunits are depicted in blue and cyan, respectively. Details are provided in the text.

DNA looping. In the case of the IIE enzymes the second DNA-bound dimer acts as an allosteric effector for cleavage at only one of the cognate sites. In analogy, we propose that two terminase protomers assemble as a head-to-head dimer of TerL subunits bound symmetrically at *cosN*. Bending of the duplex by IHF and TerS positions DNA such that it can interact with a second dimer to afford an activated dimer-of-dimers nuclease complex, as depicted in Fig. 4.

In contrast, the type IIF enzymes similarly assemble as a dimer of dimers, each bound to a cognate recognition sequence and *both* sites are cut by the activated enzyme. Within this context, “synapse” initiation models have been proposed in the phage T4 and T7 systems where it has been suggested that the maturation complex binds to two sequential *pac* sequences in the DNA concatemer, separated by one genome length. Thus, it is feasible that in the context of a multi-genome concatemer, a λ terminase dimer of dimers interacts with two sequential *cos* sequences (separated by 48.5 base pairs) to engender an activated synapse maturation complex as proposed in other systems. Indeed, this model has been previously considered in phage λ .

Genome Maturation Summary

A central dogma is that all dsDNA viruses that package DNA from multi-genome concatemers, from phages to herpesviruses, initiate the process by assembling a maturation complex at a specific initiation site; however, these complexes remain poorly studied and ill-characterized in most systems. All of the characterized viruses encode a TerS subunit that is essential to virus development *in vivo*. Presumably, this reflects the role of TerS in recognition of a specific packaging sequence present only in the viral genome and the assembly of TerL into a catalytically competent nuclease complex, the first and essential step in genome packaging. In this regard, it is noteworthy that phage T4 destroys host DNA and synthesizes viral concatemers that contain 5-hydroxymethyl-cytosine in place of cytosine. In this case, a *pac*-like sequence is not formally required to specifically recognize viral DNA since host DNA does not exist. Nevertheless, T4 TerS is required for packaging concatemeric DNA both *in vitro* and *in vivo*, despite the fact that a defined *pac* sequence is not apparently required to initiate the process. This likely reflects a TerS requirement for maturation complex assembly and duplex cleavage in a concatemeric substrate and/or subsequent motor assembly. Whatever the case, given the conservation of structure and function of the terminase enzymes, the λ terminase maturation complex, which has been extensively characterized, provides a wealth of information that can be generalized to all of the dsDNA viruses.

The Genome Packaging Complex

Assembly of the Packaging Motor

The next step in the packaging pathway is binding of the maturation complex to the portal vertex of an empty procapsid to afford the packaging motor complex (see Fig. 1). While there is some controversy with the motor orientation in phage T4, genetic, biochemical and structural studies have localized procapsid binding residues to the C-terminus of λ , P22 and T3 TerL subunits, and also in the ϕ 29 packaging ATPase. Thus, it has long been presumed that the packaging motors are composed of TerL subunits assembled in a ring-like complex oriented in a parallel manner such the C-terminal portal interaction residues directly bind to the portal ring. In contrast, it is generally presumed that the *maturation* complex orients the TerL subunits in a head-to-head arrangement for symmetric nicking of *cos*, as depicted in Fig. 4. This begs the question as to how a head-to-head maturation complex resolves this symmetry issue in the transition to a parallel packaging motor complex. Based on kinetic and biochemical data, we propose the following plausible mechanism for “*symmetry resolution*” in phage λ (Fig. 5).

Subsequent to duplex nicking, the strand-separation activity of the maturation complex ejects the upstream D_R strand; this results in the loss of DNA binding energy by the *upstream* protomers. Next, the upstream protomers flip into a parallel orientation with all of the TerL subunits bound to the newly formed D_L end. This conformational reorganization is driven by cooperative binding of the TerL subunits to the downstream DNA, plus TerS self-association interactions, mediated by the hydrophobic helix as discussed above (see Fig. 2). This resolved conformation (1) projects the C-terminal procapsid binding residues of TerL in a parallel orientation for direct and cooperative binding to the dodecameric portal complex and (2) affords an oligomeric TerS ring-like structure that is conserved among the published structures of TerS subunits (*vide supra*).

Fig. 6 Model for *cos*-clearance – the transition to a translocating motor complex. Several changes must occur for *cos*-clearance, as summarized in the Figure. The allosteric NXP binding site in TerS may serve as a “nucleotide switch” that modulates DNA binding, nuclease and packaging ATPase catalytic activities to promote the transition. Details are described in the text.

cos-Clearance: Transition to a Translocating Motor

Once the motor complex has been correctly assembled at the portal, a series of events must occur to transition from a stable complex specifically bound at the genome end, to a dynamic translocating motor complex. We refer to this transition as “*cos*-clearance” in analogy to RNA polymerase clearance from the promoter and the transition to processive RNA synthesis. Again, the λ system provides insight into this essential process as depicted in Fig. 6; (1) IHF specifically bound at the *I1* element of *cosB* must release from the duplex and (2) TerS, site-specifically bound to the *R3* and *R2* elements of *cosB* must switch to a non-specific DNA binding mode. This must occur to “un-bend” the DNA to provide a linear duplex for motor translocation from *cos*; (3) the TerL subunits specifically bound at *cosN* must also switch to a non-specific DNA binding mode to release the duplex end; (4) the packaging ATPase activity of TerL, which is downregulated in the maturation complex, must be activated to fuel translocation. In addition, the nuclease activity of the motor must be down-regulated to prevent damage to the duplex during translocation.

A Nucleotide Switch for *cos*-Clearance?

The molecular events leading to *cos*-clearance remain obscure, but it is clear that this requires coordinated allosteric interactions between the DNA and nucleotide binding sites in both the TerL and TerS subunits. As discussed above, several relevant kinetic interactions have been identified and characterized in λ terminase as summarized in Fig. 2. Most relevant to *cos*-clearance is the observation that nucleotide binding to the low affinity NXP binding site in TerS (1) modulates *cos*-specific vs. non-specific DNA binding interactions, (2) inhibits the nuclease activity in TerL and (3) stimulates ATP hydrolysis by the packaging ATPase site in TerL. These are the precise features required for the *cos* clearance transition and we posit that the NXP binding site in TerS serves as a “nucleotide switch” that regulates site specific DNA binding and nuclease activation versus non-specific DNA binding and motor translocation functions. Further, non-specific DNA also activates the packaging ATPase site in TerL, ostensibly by cooperative mechanochemical coupling events in the translocating motor. The mechanistic details linking this complex enzymology and the structural alterations mediating the transition to packaging remain a fertile area of investigation.

The Translocating Motor

In contrast to the maturation complexes discussed above, translocating packaging motors from several systems, including phages $\phi 29$, λ , T4 and P74-26, among others, have been examined in great detail. Several excellent reviews have described the structural and functional features of the motors and only salient points will be discussed here.

The activated packaging motors translocate along the duplex, fueled by ATP hydrolysis, inserting the DNA through the portal and into the procapsid shell. Ensemble biochemical and single molecule studies have shown that the translocating motors are highly processive and very fast. ATP hydrolysis is tightly coupled to motor translocation (mechanochemical coupling) and it is commonly accepted that 2 bp DNA are packaged per ATP hydrolyzed by the terminase enzymes. The motor subunits are tightly coupled and incorporation of a single defective subunit into the motor poisons translocation activity. The motors can generate an astounding ~ 60 pN force and package DNA to near crystalline density within the capsid shell.

Structure of the Translocating Motors

Despite the strict requirement of TerS *in vivo*, structural studies in the T4 and T7 systems suggest that functional headful packaging motors can be assembled as pentamers of TerL subunits assembled at the portal vertex, in the absence of TerS. Pentameric TerL

motors have also been proposed in the P74-26 and D6E systems. Similarly, the phage $\phi 29$ “ATPase” can package DNA without the requirement of a TerS-like subunit, though there remains debate as to the stoichiometry of the $\phi 29$ motor complex with pentamer and hexamer motors proposed based on structural and biochemical data, respectively. In contrast, we have proposed that the functional λ motor is composed of four protomers, which includes the TerS subunit ([TerL•TerS₂]₄). This discrepancy may reflect inherent differences between headful and unit-length genome packaging motors. Alternatively, it is feasible that a fifth protomer is recruited to the tetrameric λ maturation complex at some point during symmetry resolution, procapsid binding or *cos*-clearance steps to afford a pentameric motor (see Figs. 5 and 6). Then again, it is feasible that the λ maturation complex is, in fact, a pentamer of protomers contrary to published biophysical data. We disfavor this model because while there is precedence for tetrameric endonuclease enzymes, there is to our knowledge no precedent for a nuclease complex composed of five catalytic subunits. Notwithstanding, we cannot rigorously exclude these possibilities and the physical nature of the λ maturation and motor complexes must await further structural interrogation.

Coordinated ATP Hydrolysis by the Terminase Motors

Single molecule studies of phage $\phi 29$ and λ motors suggest that non-cooperative ATP binding appears to be associated with motor translocation (Hill coefficient, $n \sim 1$). This observation is a central feature of a mechanistic model describing mechanochemical coupling by the motors, based high resolution data in the $\phi 29$ system, as follows. A pentameric motor is assumed and ATP binds to each of the subunits in a dwell phase. This is followed by a sequential but tightly coordinated hydrolysis of four ATP's, which is proposed to “mask” cooperativity in ATP binding and/or hydrolysis *when measuring motor translocation*. Each hydrolytic event is coupled to the translocation of 2.5 bp into the capsid, for a total of 10 bp per motor cycle; the fifth motor subunit is postulated to “maintain a grip” on the duplex during each catalytic cycle.

In contrast to the single molecule studies, kinetic studies of solution-based steady-state ATP *hydrolysis* by the phage P74-26 TerL subunit (under non-packaging conditions) exhibits modest cooperativity (Hill coefficient, $n = 1.7$). Similarly, solution-based ensemble studies have characterized ATP hydrolysis by the translocating λ motor, composed of both TerL and TerS subunits, which reveal strong cooperativity in ATP hydrolysis ($n = 3.8$). How can these observations be reconciled with the apparent non-cooperative ATP binding events observed in the single molecule studies?

A critical distinction between the single molecule and solution-based ensemble biochemical studies is that the former does not actually measure ATP *hydrolysis*. Rather, the single molecule studies examine *motor translocation* as a function of ATP concentration. Thus, the discrepancy may reflect what is actually observed by the two approaches. Alternatively, it is feasible that the $\phi 29$ motor, which packages genome monomers, is mechanistically distinct from those that package DNA from a genome concatemer. Resolution of this question must await high-resolution single molecule studies of additional terminase enzymes, such as λ , T4 and P74-26, among others, to verify the results observed in the $\phi 29$ system.

Mechanochemical Coupling and DNA Translocation

While extensively studied, the molecular mechanism coupling ATP hydrolysis to duplex translocation remains speculative and several models have been proposed. These include an “inchworm” translocation model, similar to those describing translocation by monomeric and dimeric helicase enzymes. In this model, the TerL nuclease and ATPase domains both bind DNA and conformational switching between a “tense” and “relaxed” state, driven by ATP hydrolysis; this mediates sequential steps of DNA binding and release by the two domains, which drives translocation. A second “lever” hypothesis proposes that duplex translocation is mediated solely by the ATPase domain, which grips and translocates DNA in the central channel of a ring-like motor complex. In this model, ATP-hydrolysis alters the conformation of the lid subdomain, which is propagated with a “lever-like” motion to the adjacent subunit in the motor, driving duplex movement. Within this context, recent studies in the λ system suggest that TerL undergoes a “tight binding transition” upon ATP binding that is required for both tight ATP binding and tight gripping of the DNA. Further, molecular dynamics studies suggest a general terminase mechanism wherein the conserved ASCE catalytic glutamate and a conserved WA arginine act in concert to facilitate this “open” to “closed” transition, which juxtaposes the catalytic glutamate and a water molecule proximate to the γ -phosphate of ATP for catalysis. After hydrolysis and P_i release, the arginine “toggles” to interact with a different glutamate in the lid subdomain to communicate the nucleotide-bound state, which has been implicated in mechanochemical coupling. Analogous models have been proposed for the $\phi 29$, T4 and P74-26 packaging motors based on single-molecule and biochemical data.

The above models presume that the DNA is an “inert” substrate during translocation; however, other models suggest that the DNA itself plays a direct energetic role in duplex translocation. A “crunching” model proposes the motor compresses B-form DNA into a shorter A-conformation, mediated by ATP hydrolysis. Subsequently decompression back to a longer, B-form duplex propels the DNA into the shell. A related “scrunching” model proposes that the motor proteins repeatedly dehydrate and rehydrate sections of DNA, which undergo a cyclic shortening and lengthening transition. In both these models, the motor, which includes both terminase and portal proteins, capture the shortening-lengthening transitions to bias movement of the duplex into the shell interior. Finally, a novel model invokes an “osmotic pump” mechanism wherein expansion/contraction cycle of the capsid, mediated by ATP hydrolysis, “sucks” the duplex into the shell.

Given that the mechanism of coupled ATP hydrolysis and DNA translocation in terminases remains vague, few of the above models are mutually exclusive.

Termination of Packaging

Upon insertion of a full-length genome into the capsid, the translocating motor stops, cuts the duplex and ejects the stable terminase•concatemer complex, shortened by one genome length, from the genome-filled nucleocapsid. Minimally, this requires downregulation of the packaging ATPase site (to avoid motor movement) and re-activating the nuclease activity of TerL. Further, the parallel orientation of TerL subunits in the translocation motor must switch back to a head-to-head conformation (symmetry resolution), which is the presumed conformation for a catalytically competent nuclease complex (*vide supra*). As with all ill-characterized processes, several models have been proposed for this conserved process.

The first, based on structural data in phage T4, is that the nuclease catalytic site of TerL is separate and distinct from the DNA binding site involved in duplex translocation. Upon packaging the genome, the duplex is transferred from the translocation binding site to the nuclease active site. Another model, based on structural data in the P74-26 system, proposes that the TerL nuclease domain is bound to the portal ring during packaging and is sequestered from the DNA. Upon insertion of the full genome length, the nuclease domains release the portal and bind to the duplex to catalyze cleavage. Both of these models suggest that nuclease activity is “regulated” by sequestration of the catalytic site from the DNA during translocation. This begs the question as to what regulates the conformational changes that allow duplex access to the nuclease site.

Single molecule studies have demonstrated a dramatic slowing of the packaging motors at high packaging densities. The simplest model is that motor slowing provides sufficient time for a slow conformational change that allows duplex transfer to the nuclease site. This kinetic model is analogous to DNA strand switching from the polymerase site to the exonuclease editing site in DNA polymerase enzymes. The model predicts that duplex cutting would occur whenever the translocating motor pauses; however, a number of studies do not show evidence for cutting by a stalled motor. Thus, the termination signals appear more complicated and alternative models propose that shell filling density is directly communicated from the nucleocapsid to the translocating motor. These models suggest that the portal serves as a “packaging sensor” that allosterically activates TerL nuclease activity to allow for headful cleavage.

Unit Length Packaging Motors

The situation is more complicated with viruses that package unit-length genomes, such as λ , HK97 and $\phi 80$, among others. In these cases, upon arrival at *cos* and with attenuated motor velocity, the motor subunits must specifically engage the *cos*-sequence prior to nuclease activation (*cos*-capture). Again, phage λ provides a useful model to understand *cos*-capture and the terminal *cos*-cleavage reaction, as depicted in Fig. 7.

Upon arrival at the terminal *cos*, ATPase activity must be downregulated and nuclease activity must be activated in the switch from a dynamic motor to a stable nicking complex. Nuclease activation is likely concomitant with resolution of the motor symmetry to again bind to a symmetric *cosN* nicking site. Specifically, the “parallel” motor complex must switch back to a “head-to-head” complex symmetrically disposed at *cosN* for duplex nicking. We presume that the regulatory ATP binding site in λ TerS (Fig. 2) is involved in this transition, but data is limited.

Feiss and co-workers have proposed that specific elements within the *cos* sequence also play important roles in terminal symmetry resolution and *cos*-capture steps, as follows. Genetic and biochemical studies have identified a *cosQ* element upstream of *cosN* and an I2 IHF binding element between *cosN* and *cosB*, that are essential for terminal *cos*-capture (Fig. 7). When mutations are introduced into *cosQ*, the translocating motor nicks the top strand of *cosN*, but not the bottom strand and the motor continues to package DNA until the capsid is filled to capacity. These mutations are lethal because uncut DNA protrudes from the portal and tails cannot be attached. The observation that only the top strand is nicked in the presence of *cosQ* mutations suggest that this element is required for symmetry resolution steps in the transition from a parallel motor complex to a head-to-head nuclease complex capable of symmetric nicking of the duplex.

Genetic characterization of *cosQ* mutations reveal three modes of suppression; (1) compensating mutations in *cosQ*, (2) an increase in genome length (4–5 kb), which requires IHF and (3) missense mutations within the portal gene. It has been proposed that genome length and portal mutations serve to slow the translocating motor and increase the efficiency of *cosQ*-*cosN*-I2 capture. In this model, *cosQ* serves as a molecular “speed bump”. This is consistent with the observation that unit-length terminase enzymes retain a “headful” component to packaging termination; the efficiency of cleavage at the terminal *cos* sequence in λ decreases from 100% to 75% as the genome is shortened to ~80%. Further, insertion of additional *cos* sequences upstream of the natural termination site do not induce premature nuclease activity and the aggregate data indicate that *cos*-capture requires specific signals in the DNA plus sufficient capsid filling densities. Genetic studies further suggest that the portal may serve as a packaging sensor, transmitting information on packaging density to the TerL subunits in the translocating motor, as has been proposed for the headful packaging motors. Thus, the termination signals include *cosQ*-*cosN*-I2 elements that are likely recognized by the translocating portal-terminase complex and IHF and by attenuated motor velocity.

Terminase Ejection and Virion Completion

Once terminase has nicked the strands within the terminal *cosN* element, the strand separation activity of terminase is poised to release the DNA-filled nucleocapsid and regenerate the maturation complex, as depicted in Fig. 7. This begs the question as

Fig. 7 *cos*-capture and the terminal cleavage reaction. The translocating λ motor slows at high packaging densities to allow terminase binding to *cosQ-cosN* elements, presumably enhanced by IHF binding to the *I2* element. This requires symmetry resolution of the TerL subunits from a parallel orientation in the motor to a head-to-head orientation in the activated nuclease complex. Finishing proteins likely displace the terminase-DNA complex from the nucleocapsid, which affords an infectious virus upon addition of a pre-assembled tail. Note that the matured genome end (D_R) extends from the capsid into the tail tube of the assembled viral particle. The ejected terminase•DNA concatemer complex, formally equivalent to the maturation complex that initiated genome packaging, again undergoes a symmetry resolution transition and binds another procapsid to initiate a second round of DNA packaging.

to how the highly-pressurized packaged DNA is retained within the shell subsequent to terminase release. One model proposes that the portal ring binds tightly to the duplex as a “one-way valve” to prevent release. Additionally, it is feasible that “finishing proteins” that add to the portal of a DNA-filled shell actually play a direct role in ejection of the terminase•concatemer complex, simultaneously stabilizing the DNA-filled shell. Whatever the case, the ejected terminase•concatemer complex, formally equivalent to the complex that initiated genome packaging, again binds to an empty procapsid shell to initiate the next round of processive packaging. In this manner, terminase alternates between a stable maturation complex and a dynamic motor complex.

Conclusion

Herein I have proposed specific molecular events in phage λ required for the site-specific assembly and activation of a stable maturation complex and its transition to a dynamic packaging motor including “symmetry resolution”, procapsid binding and *cos*-clearance steps. We discuss current models that describe motor translocation and mechanochemical coupling of ATP hydrolysis and complex movement. Finally, we discuss the features and mechanistic complications involved in the terminal *cos*-cleavage reaction, including the signals required for *cos*-capture, symmetry resolution and activation of nuclease activity. The terminase enzymes must sequentially cycle between these two complexes, stable nuclease and dynamic motor, to allow processive genome packaging from a concatemeric DNA substrate. The proposed models derive from extensive genetic, kinetic, biochemical and biophysical data obtained over decades of study in our lab and by others. Kinetic and thermodynamic interrogation of λ terminase figure prominently in the development of the models and complement the structural and single-molecule data published in λ and many other systems. Analogous assembly steps and catalytic transitions must occur in all of the dsDNA viruses that package monomeric genomes from concatemeric precursors and while details of these processes may differ, it is likely that the general features proposed for λ are recapitulated in all of the terminase family members. Thus, continued mechanistic interrogation of the packaging complexes using integrated genetic, structural, biophysical, enzymological and computational approaches is warranted. Indeed, the availability of multiple packaging systems including λ , T4, SPP1, P74-26, SF6, among others, provides an attractive pallet from which to choose and define conserved features and system-specific mechanisms of packaging amongst the terminase enzymes.

Glossary

Affinity Description of the interaction between two components of a binary complex that can be qualitatively referred to as either strong/tight or weak. Usually this is defined quantitatively as the equilibrium dissociation constant.

Avidity The increase in affinity that occurs as each new binary interaction is made between additional components of the final ternary complex.

Capsid or phage head The protein shell that is preassembled from the major capsid protein into which the viral genome is packaged. In non-enveloped viruses this forms the outside of the virus and eventually acts as the protective container for transfer of the viral genome to a new host.

Concatemer The nascent dsDNA product from rolling circle replication of viral genomic DNA that is a continuous dsDNA strand with multiple copies of the genome fused head to tail.

Conformational recognition The situation where assembly of a protein-DNA complex is facilitated by electrostatic attraction between oppositely charged surfaces that have complementary shapes, and the ability of the target DNA sequence to form the matching shape. Since contact between the protein and DNA base pairs are not

directly sequence identifying, this type of binding is an indirect readout of the underlying sequence.

Genome maturation The process where the concatemeric viral DNA is recognized and cut to create the free DNA end that is key for insertion into the capsid pore at the start of packaging.

Headful termination The DNA sequence independent termination of the DNA translocation reaction that occurs once the capsid reaches maximum DNA capacity. The DNA stalled within the molecular motor is cut by an endonuclease domain of the motor protein. The entire motor assembly (DNA bound to ATPase) is then transferred to a new empty capsid and the packaging process is repeated.

Packaging The process where the nascent genomic DNA is pumped into an empty capsid shell to form a new infectious virus particle or virion.

Replication The process in which new copies of the viral genome are synthesized for the creation of new virus particles.

Sequence specific binding The binding interaction between a protein and a defined sequence of DNA, mediated by specific hydrogen bonding contacts between the side chains of the recognition amino acids on the binding surface and the edges of the individual base pairs in the DNA sequence.

Introduction

Bacteriophages repurpose the host cell's machinery to make the specialized molecular machines and macromolecular complexes required to produce new virus particles: a copy of the viral genome encased in a protective protein container known as a capsid or phage head. These new viruses are then released and can infect other bacteria. The nascent copies of the bacteriophage genome produced during replication need to be pumped, by a powerful DNA translocation motor, into pre-assembled capsids through a specialized pore. The packaged DNA forms concentric loops of decreasing diameter around the inside of the capsid until the strands of DNA are tightly packed against each other. As the phage head fills, the translocation motor continues to force DNA into the capsid, driving the ordered bending and stacking of the DNA against the massive physical forces that normally prevent such compaction. Indeed, the pressure of the restrained DNA inside the packaged virus is 10 times greater than the pressure contained

Fig. 1 Overview of dsDNA bacteriophage genome packaging systems. The phage genome is assembled with a powerful DNA translocation motor (red) on a unique pore (portal or connector protein; gray) in the preformed protein capsid. ATP hydrolysis powers the macromolecular machine that pumps the viral genomic DNA into the protective viral shell in a process known as packaging. (A) Protein primed replication of linear dsDNA genomes produce (e.g., *Bacillus* phage ϕ 29 and *Tectiviridae* e.g., PRD1) create monomeric dsDNA products fused to terminal protein (green). (B, C) Rolling circle replication of a circularized template intermediate yield long polymeric concatemers of dsDNA genomes, fused head to tail, that need to be cut (arrows) to create the free DNA end required for packaging into empty capsids. Once the capsid is filled, the DNA is cleaved again and the motor-DNA complex is transferred to a new empty capsid and the process is repeated. (B) Packaging of unit length genomes mediated by *cos* sequences (*E. coli* phage λ or HK97; orange) or terminal repeat sequences (*E. coli* phage T3, T5, T7). (C) The headful packaging mechanism is initiated by a cleavage at the *pac* site (cyan) and terminated at non-specific sequences after ~104% of the genome has been packaged (arrows), producing virions containing slightly different circularly permuted genomes.

in a champagne bottle. This DNA packaging process is started when one end of the viral genome is assembled into the ATP hydrolysis powered DNA translocation motor located on the capsid pore (known as either portal or connector, Fig. 1).

Like all cells, the inside of a bacteria cell is a densely crowded dynamic environment, in which the genomic DNA is stored in ordered structures. The macromolecular machinery that rearranges, copies, repairs and transcribes the information coded within the genome are integrated within this superstructure. Additionally, bacteria also contain other large biomachines, such as ribosomes, proteasomes, and the complexes that drive metabolism, all of which are mixed together with individual protein molecules, nutrients and metabolites into a molecular stew with the consistency of a gummy bear candy. Virus replication and packaging occurs within this complex environment. Consider the case of an average *E. coli* cell in exponential growth, containing: ~2 copies of its own DNA genome; a high copy number average sized plasmid DNA ~100 copies of 5 thousand base pairs (bp); and up to 300 new copies of a replicating phage DNA genome (~50 thousand bp); equating to a total DNA composition of ~5 million base pairs. How does an infecting bacteriophage recognize and selectively package its own genomic DNA?

Genome Replication and Selection Mechanisms

The problem of preferential packaging of phage genomic DNA, rather than host genomic or plasmid DNA, can be overcome through several different methods. While some bacteriophages (e.g., *Pseudomonas chlororaphis* phage 201 ϕ 2-1) keep their replication machinery and the newly synthesized genomes separate from the host cell genome within a virally encoded protein compartment, most rely on some form of selective recognition between host or viral DNA and virally encoded proteins. For example, *E. coli* phages T4, T3, and T7 produce nuclease enzymes that target and degrade the host cell DNA, leaving only the nascent viral DNA to be packaged. However, the most common mechanism uses dedicated viral proteins that selectively bind to bacteriophage genomic DNA, and then direct the assembly of the packing motor-DNA complex, onto the portal of the capsid, to initiate DNA packaging. Since double stranded (ds) DNA bacteriophages use different replication systems to make new copies of their genomic DNA and thus produce diverse dsDNA products, specialized mechanisms are required for specific recognition of these replication products in order to initiate packaging.

Monomeric replication products

Bacteriophages that use protein-primed replication (*Bacillus* phage ϕ 29 and *Tectiviridae* e.g., PRD1) produce linear monomeric dsDNA genomes. The products of this type of replication are most obviously defined by the presence of a protein covalently attached to the terminal 5' phosphate at each end of the genomic dsDNA. This terminal protein (TP) remains attached to the nascent DNA strand after acting as the protein primer for initiation of strand synthesis by the bacteriophage DNA polymerase (Fig. 1(A)).

Concatemeric replication products

New copies of most linear bacteriophage dsDNA genomes are produced through rolling circle replication of a circularized template intermediate (e.g., *E. coli* λ and T3 bacteriophages). This results in a concatemeric genome product: multiple copies of the genome, joined head to tail in a single long dsDNA strand. In a process known as genome maturation, these fused copies must be separated

at the start of each individual genomic unit, in order to create the nascent DNA end that is key for loading into the packaging motor. Since many of these viral packaging systems show no genome preference when provided with a free dsDNA end *in vitro*, the protein participants that generate the nascent DNA end, play an important role in genome selectivity. Several different methods for achieving this genome maturation process have been noted.

Some phages package exactly one genome unit length defined by cohesive end site (*cos*) sequences (*E. coli* phage λ or HK97) or packaging (*pac*) sequence encoded direct terminal repeat (*E. coli* phage T3 and T7) sequences. Other phages package circularly permuted genomes (e.g., *Bacillus* phages SF6 and SPP1, and *Salmonella* phage P22), with the initial cleavage defined by a *pac* sequence site, resulting in packaging of greater than 1 genome unit length. After the initiation event at the *pac* site, when at least one genome length of the concatemeric DNA has been pumped into the phage head, DNA translocation is terminated by another cleavage event and the motor-DNA end complex is transferred to a new empty capsid to begin the packaging process again (Fig. 1(B)). This secondary, 'motor transfer' mode of packaging initiation accounts for at least two thirds of all packaging events in bacteriophages that use rolling circle replication.

Bacteriophages that package unit length genomes, such as λ or HK97, terminate DNA translocation and cut the DNA at the same specific sequence motif (*cos*) in the next adjacent genome. However, viruses that package more than one genome length (~104%), terminate packaging at non-sequence specific sites using a 'headful' mechanism (Fig. 1(C)). Headful cleavage is presumably mediated by the deceleration of the packaging rate that results from the mounting internal pressures that are induced as the capsid approaches maximal DNA capacity. Indeed, this headful signal for termination of translocation appears to be an underlying physicochemical property of dsDNA bacteriophage packaging systems, as it has also been observed in mutant versions of viruses that usually package unit length genomes.

Despite these differences, in each case, initial genome end processing and motor assembly requires specific recognition of the viral genome by virally encoded proteins. This selective binding relies on the physical properties of the targeted DNA: the average base composition and/or modifications, local and global variations in shape, and the presence of specific sequence motifs.

The Shape of DNA

The helical architecture of dsDNA is stabilized by both the hydrogen bonds formed between the complementary Thymidine: Adenine (A:T) and Guanosine:Cytosine (G:C) base pairs at the center of the two sugar-phosphate backbone chains, and the helical stacking interactions between adjacent bases along each strand (Fig. 2(A)). Double stranded DNA is a conformationally dynamic molecule that can exist in many different shapes or forms. The most commonly adopted shape is the 'B-form' that has an average of 10.5 bp per helical turn, creating wide major and narrow minor grooves of equal depths. Since the minor groove is on the sugar-phosphate side of the bases where access to the bases is more sterically hindered, sequence specific interactions occur in the major groove. Additionally, the minor groove of ideal B-form DNA is also comparatively more electrostatically negative than the major groove. While B-form DNA is the most prevalent form within cells, DNA conformation is both dynamic, fluctuating locally between conformational variants, and dependent on sequence, so that some sequence patterns are more likely to enter different conformations. For instance, A-rich sequences form non-ideal B-form DNA with more narrow minor grooves, while GC-rich DNA sequences are often found in 'A-form' shapes (Fig. 2(A)). A-form DNA is shorter and wider, with a looser helical turn (11 bp per turn) creating a deep narrow major groove and a wide shallow minor groove. The extent of hydration of DNA, and the resulting hydrogen bonds formed with water molecules along the phosphate backbone and within the major and minor grooves, is crucial in determining these conformations. Indeed, dehydration of B-form DNA sees a transition to A-form. Further conformational variants are formed by weakening of the hydrogen bonds between base pairs (breathing or melting) resulting in the formation of single stranded (ss) regions such as found in bulges, bubbles or loops. Perturbation of the base stacking interactions and rotation of the backbone strand allows bases to 'flip out' of the helical structure. These variants can be further stabilised and/or induced by local DNA base sequence or protein binding interactions. Over longer distances, such sequence induced local conformational changes in the DNA helix can contribute to curvature of the DNA helix over a single basepair (kinking) or several base pairs (bending) (Fig. 2(B)), conformations which can be sharply bent by the binding of histone-like proteins in bacteria (Fig. 2(C)). When multiple repeats of these sequences occur in defined patterns, the DNA can be curved into circular or superhelical structures, as observed in nucleosome core particles (Fig. 2(D)). These conformations are also somewhat dependent on the base sequence composition, as well as the binding of counter-ions or proteins. Globally, the action of macromolecular machines that separate the DNA strands during RNA transcription or DNA replication, cause the helical dsDNA to become supercoiled (Fig. 2(E)). Positive supercoils, where the DNA is overwound and less likely to melt into individual strands, are formed in front of the advancing enzyme complex, while negative supercoils (underwound DNA with a higher propensity for melting) are formed behind it. Negatively supercoiled DNA is thought to exist as Z-form DNA (Fig. 2(A)), where the phosphate backbone has a zigzag conformation and the stacked bases are exposed towards the outer edge of the fiber. These differently shaped DNA structures can also be specifically bound by specialized proteins using conformational recognition.

Double stranded DNA is a surprisingly versatile information storage device. At its most basic, it contains the ordered sequence of bases that comprise the code, or blue print, for each of the RNA and protein components of the molecular machinery that perform the processes necessary for organism survival. Overlaid around, and sometimes over, this basic code are the sequence patterns, or motifs, that act as signals that are preferentially bound by the protein complexes that copy or transcribe the basic code, or control these processes. Redundancy in the code leads to variation in the average base composition between organisms, and the

Fig. 2 The conformational variation of DNA. (A) Cartoon depiction of the DNA double helix in A-, B- and Z-form conformations (top panel), showing the sugar-phosphate backbone (orange ribbon; and gray rings), base pairing between complementary bases (blue/white/red shaded rings) and the helical stacking interactions between bases along the same strand (bottom panel). Surface cartoons show the distance from the center of the DNA helix in a gradient colored from dark gray (center) to orange (10 Å from helix center). Models were created from fiber diffraction data using 3DNA (x3DNA.org). Cartoon depiction of: (B) bending (PDB 1LMB) or kinking (PDB 1JJ4) of dsDNA stabilized by proteins; (C) sharply bent DNA bound to Integration Host Factor (PDB 1IHF); and (D) tightly coiled circular DNA in nucleosome core particles (PDB 3LZ0). (E) Representation of positive and negative DNA (orange) supercoiling that occurs during transcription by RNA polymerase (blue).

over- or under- representation of certain patterns, the bases of which are sometimes specifically targeted for chemical modification (e.g., methylation) by dedicated proteins. The conformational repertoire of helical dsDNA introduced by particular sequences of base pairs, as well as the contribution to larger shape variations by repeating patterns of such sequences, can be considered as an additional 'conformational code' that can be specifically acted upon by protein cofactors with complementary shaped binding surfaces. Combination of sequence specific binding with conformational recognition can significantly expand the protein binding code available to a DNA sequence.

Fig. 3 Examples of preferential DNA-protein interactions. (A) Cartoon image of sequence specific binding to B-form DNA by a Helix-Turn-Helix (HTH) motif (PDB 1WOT), showing the recognition helix (green), the support helix (yellow) and an example of an arginine rich N-terminal arm (magenta). (B,C) Image showing modes of conformational recognition using positively charged protein surfaces with complementary shapes to the bound DNA. The electrostatic surface potential for each protein is depicted (positive, blue; and negative, red). (B) *E. coli* Integration Host Factor (IHF) bound to H-box DNA, and (C) a nucleosome core particle bound to bent DNA. In all frames the phosphate backbone (orange strands), ribose sugars (gray rings) and nucleotide bases (gray, red, blue rings) of the DNA are shown.

Protein-DNA Binding

A Question of Fidelity: Sequence Specific and Non-Specific Binding

Protein binding interactions with nucleic acid molecules are considered sequence-specific when they are stabilised by hydrogen bonding networks or hydrophobic interactions between the amino acid side chains of the protein and the individual base pairs of the DNA sequence motif. This is also known as direct readout. Additional non-sequence specific binding interactions occur around the sequence specific contacts. These largely electrostatic connections between the positively charged amino acids forming the binding surface of the protein and the negatively charged sugar-phosphate backbone of the DNA, serve to stabilize the bound complex. Indeed, the comparatively weak non-sequence specific binding interactions can play an important role in localizing the protein to the DNA, allowing the protein to slide randomly along the dsDNA in a linear search for a sequence specific binding motif. Conformational changes in both the protein and the DNA allow direct contacts to be made with the bases of the binding sequence motif, increasing the affinity of the protein for the DNA at this sequence. Despite not making identifying contacts with the base pairs in the major groove, the overall shape of the positively charged surface of the protein can also play a role in selective binding to segments of DNA with a potential for matching this shape. This indirect readout mode has been noted in the sharply bent or superhelical protein-DNA complexes of genome architectural proteins.

DNA Binding Domains

Many proteins interact with DNA through discrete domains, known as DNA binding domains (DBDs). These are often folded independently of the main protein body and can be swapped between proteins or studied in isolation. DBDs are found in different shapes, also known as folds or structural motifs, depending on the functional requirements of the core protein or complex. DBDs that interact with specific DNA sequence patterns have folds that allow placement of the binding surface so that direct contacts can be made between the residues of this surface and the individual bases that comprise the binding sequence. These include: Helix-Turn-Helix (HTH); Helix-Loop-Helix; Zinc fingers and Leucine zippers, among others. Additional non-sequence specific contacts are often made by extensions to the DBD that are not always considered part of the core DBD motif. Proteins that use a conformational recognition mode for binding to targeted DNA sequences have core structures that place the DNA binding features in a defined geometry to allow non-sequence specific contacts with the sugar-phosphate backbone or the minor groove of DNA of a distinct shape, such as the histone complexes of eukaryotes and the histone-like proteins of bacteria.

HTH motifs are highly conserved and widespread throughout nature, including in bacteriophages. The core domain is usually presented on a small helical bundle and consists of 2 α -helices, connected by a turn, and held tightly together in a cross shape by conserved hydrophobic contacts between the helices. Since an α -helix is just wide enough to lie along the major groove of B-form DNA when aligned roughly parallel to the backbone strands, the recognition helix (usually the second in the HTH) affords a compact scaffold from which to project the combination of amino acid side chains that will contact the base pairs within the major groove and bind specifically to the target sequence. The amino acid residues around this helix assist with correctly positioning the base specific contacts through additional non-sequence specific contacts with the dsDNA backbone. Common extensions to this core fold, such as N-terminal arms and/or an anti-parallel β -sheet wings, such as in the winged HTH (wHTH), make electrostatically mediated contacts with the sugar-phosphate backbone and/or the minor groove (Fig. 3(A)).

Conformational recognition, such as used by genome architecture proteins, uses larger protein assemblies with surfaces of defined geometry and patterns of positive charge to capture and stabilize transient DNA shapes. For instance, histone-like proteins

(e.g., Integration host factor, IHF) of bacteria bind as dimers in a non-sequence specific manner to DNA that has a propensity for forming sharp bends, stabilizing the bend and assisting in wrapping and condensing the DNA chromatid. The protein dimer creates a positively charged, saddle-shaped β -sheet surface that is suspended between two flexible extended β -ribbon arms that lie along the minor groove when bound to DNA. The tips of the arms display conserved proline residues that stabilize the kinked DNA conformation by projecting between two stacked T bases and distorting the helical assembly of base pairs. IHF binds preferentially to DNA sequences in a conformational recognition mode where the spacing between short sequences of conserved base pairs is required for placing narrowed minor grooves at the correct position for interaction with distinct features of the protein (arginine residues along the arms). Electrostatic interactions between the bent DNA strands and the saddle groove over the top of the protein and down the side of the protein further stabilize the bent conformation (Fig. 3(B)). In Eukaryotes, the histone octamers in nucleosome core particles form a somewhat asymmetric disk-like shape that is highly positively charged around the circumference so that ~ 140 bp of DNA wraps twice around the disk to form a superhelical structure. The diameter of the core is such that it selectively binds to DNA with repeating patterns of sequences (A-tracts followed by CA bases) that are kinked, stretched and bent into a tightly wrapped helical coil (Fig. 3(C)). These shapes are further stabilised by precise placement of electrostatic arginine contacts in regions of narrowed minor grooves.

The general properties of these DBDs that modulate interaction with their target DNA sequences are exploited and refined, both in phage encoded proteins and the target DNA sequences, to ensure selective packaging of the viral genomic DNA. Examples from bacteriophage packaging initiation systems are discussed below.

Strength in Numbers: Multiple Binding Events Regulate Complex Assembly

The macromolecular complexes that function on DNA assemble in a cooperative, or synergistic manner, through a network of interactions that form between the different protein components and their individual contacts with the DNA. Consequently, the DNA can be considered as acting both as a substrate, being the functional target of the macromolecular machine, and, as the scaffold on which the functional protein complex is assembled. These multiple interaction events serve to increase the overall affinity, or avidity, of the complex for DNA, above the initial binding level observed for the individual components. Such avidity stems from the apparent increase in the local concentration of the binding components that are tethered together through mutual contacts with other members of the complex. A systematic build-up of weak binding interactions in this modular fashion, not only increases the number of different specific interactions that are possible for a particular genome, but also introduces more flexibility into the range of mechanisms for regulating the formation and disassembly of the functional complexes. For instance, ligand binding and/or chemical processing can trigger conformational changes that either positively or negatively modify the binding affinity of one component for DNA or for other complex components. This modulation of affinity allows the assembly, function and dissociation of the different macromolecular machines to be coordinated efficiently during replication and packaging.

Recognition of Viral Genomic DNA

The combinatorial power of DNA sequence and conformational recognition by specialized proteins is used to ensure selective packaging of bacteriophage genomic dsDNA. This process exploits the basic properties of the different genomic replication products, leading to the variety of specific recognition mechanisms described below.

Monomeric Genomes and Terminal Proteins

In $\phi 29$, the terminal protein (TP or gp3), in complex the viral DNA polymerase, binds preferentially to the end of the dsDNA genome through recognition of the combination of the 6 bp inverted terminal repeat sequence (5'-AAAGTA-3') and the TP covalently attached at the free 5' end during the previous round of replication. The N-terminal 74 amino acids of TP are predicted to form α -helices that have been shown to non-specifically interact with either ss or dsDNA. Presumably this non-sequence specific interaction mediates formation of a loop or lariat structure where the 5'-end bonded TP loops back and binds to the same dsDNA genome molecule. Binding of the gp16 motor assembly (equivalent to the ATPase domain of large terminase) to the TP-lariat loop junction may induce or stabilize supercoiling of the DNA within the lariat loop. The nascent bacteriophage dsDNA genome is negatively supercoiled compared with the host genomic DNA by the action of replication complexes, and the formation of the lariat loop structure. This topology contributes to the conformationally selective binding of the viral genomic DNA to the capsid located connector assembly to make a complex where the DNA is wrapped around the connector. In a motion similar to a rope moving around a pulley, this wrapped DNA may slide around the connector complex until the gp16 bound TP-lariat loop junction reaches the connector and the complete motor assembly is formed at the connector/pRNA pore on the capsid (Fig. 4).

Concatemeric DNA and Terminase Proteins

Packaging of the concatemeric product from rolling circle replication is initiated when the nascent genomic DNA end is produced by a virally encoded endonuclease. This enzyme is recruited to the cleavage site by at least one other viral protein that bind(s)

Fig. 4 Model for packaging of monomeric genomic dsDNA. Cartoon model of the features required for specific packaging of ϕ 29 genomic dsDNA (orange). The 5' covalently attached Terminal protein (TP, PDB 2EX3, green) binds non-specifically to an internal segment of the genomic DNA forming a looped lariat structure. The gp16 ATPase motor (red, PDB 5HD9) binds to TP-DNA bound end of the lariat, forming or stabilizing negative supercoils in the DNA within the lariat. The connector protein (gray, PDB 1H5W; assembled into a unique vertex of the capsid, shaded background) binds the negative supercoiled DNA to form a wrapped complex.

specifically to recognition signals in the genomic DNA. These proteins are usually referred to as the terminase, or Ter, proteins, as they help define the termini of packaged DNA. The small terminase protein (TerS) binds specifically to recognition signals that mark the genome end within the concatemeric replication product. This protein-DNA complex is bound and stabilised by the large terminase protein (TerL), which contains the nuclease domain that cleaves the end of the genome as well as the ATPase domain that powers the packaging motor. The terms 'small' and 'large' are in reference to their respective monomeric molecular weights. The nascent DNA end is assembled within a pentameric ring of large terminase subunits at the portal/connector pore complex of the empty capsid, forming the powerful DNA translocation motor that pumps the DNA into the capsid shell. The mechanisms by which the initiating terminase protein complexes of bacteriophages specifically recognize, and assemble, onto their cognate genomes are described below.

Direct terminal repeats: T3 and T7

The packaged linear genomes of T3 and T7 bacteriophages are bounded at each end by terminally redundant (TR) direct repeat sequences of 230 and 160 bp, respectively (Fig. 5(A)). In concatemeric DNA, a single copy of the TR sequence is preceded by the *pac* binding (*pacB*) sequence and bounded at each end by *pac* cleavage (*pacCL* and *pacCR*) sites. The *pacB* site defines phage specific promoter sequences for the cognate viral RNA polymerase, rather than the site of TerS binding, hence coupling packaging initiation to RNA transcription of the TR sequence. Genome end maturation is triggered when an RNA polymerase transcription complex becomes stalled at the concatemer junction (CJ) pause signal downstream of *pacCR*. In a process that is still poorly understood, the corresponding viral terminase proteins (gp18 and gp19) interact directly with the paused RNA polymerase complex in order to assemble at the TR sequence and subsequently nick the dsDNA on opposite strands at *pacCL* and *pacCR*, creating long complementary 5' extensions over TR. However, given that the action of the transcription complex would also produce supercoiling in the dsDNA template, and that the T7 TerS forms an oligomeric complex of ~8 monomers, it is possible that the terminase protein complex also recognizes the global conformation of the DNA surrounding the paused transcription complex to form a stable and functional terminase assembly. The direct repeat sequences of the TR are subsequently generated through an end filling extension reaction, by a DNA polymerase from the 3' end of the nicked strand along each newly formed 5' strand until the second nicked site is reached. The nascent dsDNA end at *pacCR* is then assembled into the macromolecular motor complex for the DNA packaging process.

Cohesive ends: λ -like

In phages λ and 21, the end of the genome is defined by the *cos* sequence; a complex 200 bp region comprised of the *cosQ*, *cosN* and *cosB* sites (Fig. 5(B)). The *cosB* (binding) site is bound specifically by the terminase complex, thought to be a tetramer of protomers, where each protomer is comprised of a heterotrimer of 2 gpNu1 proteins and gpA (TerS and TerL respectively). This proteo-DNA complex directs the nuclease domain of TerL to introduce staggered cuts in the *cosN* (nicking) sequence creating complementary 12 base ss 5' overhangs at the end of each adjacent genome. The *cosQ* containing DNA is freed from the complex, and the remaining DNA end (with the *cosB* site) is assembled into the packaging motor. DNA translocation begins and continues

Fig. 5 Models of the packaging initiation processes for concatemeric genomes. In all images packaging proceeds from the cleavage site towards the right hand end of the genome as depicted. (A) Depiction of the genome recognition and packaging initiation events in T3 and T7 phages; inset: surface cartoon showing specific contacts between T7 RNA polymerase (PDB 1CEZ, light purple) and the T7 promoter *pacB* DNA (light orange) with the transcription start site depicted by the bent arrow. RNA polymerase pauses after transcription of the *pacC* Terminally Redundant (TR) sequences (dark orange) and is bound by TerL (red) which cuts the end of the *pacC* sequence. T7 DNA polymerase (green) extends the cleaved 3' ends of the DNA to create the terminal repeat sequences. It is unknown how the cleavage of the opposite end of the TR sequence occurs, or what role the octomeric TerS (gray circles) may play in this process (indicated by the arrows and question marks). (B) Cartoon image of bent *cos* DNA (orange) with bound IHF dimer (dark gray) and the tetramer of terminase protomers binding to I1 and R sites respectively (TerS₂:TerL, white and red respectively); the sequence of both strands of the *cosN* site are shown with the arrows denoting the cleavage sites. *cosN* and R site sequences are shaded in orange. The sequence coding for TerS/gpNu1 is shown in blue. (C) Diagram of T4 packaging initiation showing a model for the synapsis complex formed by two stacked TerS oligomers (white) loaded on to two different genomic segments of the concatemer (gray and blue). TerL (red) interacts with gp55 (late sigma factor, yellow) bound to the T4 DNA sliding clamp (gp45, dark gray) and a transcriptional coactivator (gp33, green). (D) Cartoon representation of genome recognition and maturation events in P22 phage. A complex of 1–3 TerL proteins (red) assembled on the TerS nonamer (white) binds to the *pac* sequence (orange) located within the *terS* gene (blue). Potential binding site of *pac* DNA (orange) located near the C-terminal end of TerS is shown by a segment of DNA. Cleavage occurs in a defined pattern with a 120 bp segment around the *pac* sequence, (arrows, length indicates cleavage frequency). (E) Representation of the recognition of Sf6 genomic DNA recognition by the HTH domains of TerS (white) of the *pac* sequence (orange) located in the *terS* gene (blue). Cleavage occurs non-specifically over a ~2000 bp region of the genome centered on the *pac* sequence, with decreasing frequency depicted by the gradient from gray (high frequency) to white (low frequency). This non-specific cleavage may be mediated by sliding of TerS wrapped DNA along the DNA strand. (F) Depiction of SPP1/SF6 *pac* site showing the *pacL* (light orange) sequence which has a propensity for bending and covers the promoter (bent arrow) regulating *terS* (blue) expression. Two TerS assemblies (white) bind to *pacL* and *pacR* containing DNA in a wrapped complex that recruits TerL (red) to cleave at *pacC*. Cleavage (arrows) occurs within a few bases of the preferred cleavage site (large arrow).

Fig. 6 HTH domains and oligomeric TerS assemblies. Top Panel: Cartoon image of the HTH domains (yellow-orange) from TerS proteins of different phages (A: λ (PDB 1J9I); B: phBC65A1 (PDB 2A09); C: T4-like 44RR (3XTS); D: P22 (PDB 3P9A); E: Sf6 (PDB 4YDQ); F: SF6 (PDB 3ZQ); G: G20c (PDB 4XVN)) aligned with the SF6 DBD (PDB 4ZC3, blue). The support and recognition helices for the SF6 DBD ($\alpha 2$ and $\alpha 3$ respectively) and P22 TerS ($\alpha 3$ and $\alpha 4$, respectively) are labeled. Middle Panel: Ribbon diagram of the oligomeric assemblies of the TerS with the DBDs highlighted by yellow circle and the number of monomers in the assembly listed above. Bottom panel: Image of the electrostatic surface potentials of circular TerS oligomers, showing areas of positive (blue) and negative (red) charge.

until the *cos* sequence in the next adjacent genome reaches the motor. At this point, the *cosQ* motif assists to terminate the packaging process, promoting cleavage at the subsequent *cosN* site and the DNA/motor complex is transferred to an empty capsid for the ensuing round of packaging. Assembly of the terminase complex onto the *cosB* sequence during the initiation process utilizes both DNA sequence specific and conformational recognition.

Crucial to the assembly of the active terminase complex at the *cosB* site is the specific interaction of the IHF dimer, with the I1 subsite (27 bp) located equidistant between the essential TerS binding sites (inverted repeats R3 and R2). As expected, IHF binding introduces a sharp hairpin-like bend ($\sim 160^\circ$) in the I1 segment of dsDNA which places the R2 and R3 motifs directly opposite each other on the inside surfaces of the bent dsDNA strands. This IHF stabilized conformation promotes the cooperative assembly of the final tetrameric protomer (TerS₂-TerL) assembly that is tightly bound to the R2 and R3 sequences, possibly through one TerS subunit from each of two protomers (Fig. 5B). The remaining two protomers in the tetrameric complex are likely bound to DNA at the non-canonical R3 and *cosN* or *cosQ* (also known as R4) sites by weak DNA binding interactions and the increased local concentration generated by the tetrameric complex bound with high affinity to the canonical R2/R3 sequences on the same dsDNA hairpin scaffold. Cleavage at *cosN* by TerL creates an intermediate complex where the *cosQ* containing DNA fragment is only weakly bound to a single protomer and no longer benefits from the cooperative affinity mediated by a continuous uncleaved strand of dsDNA. This results in the release of the *cosQ* containing DNA from the assembled tetramer of TerS₂-TerL protomers bound to the nascent end of the genome.

Molecular detail of the contacts between components of the terminase complex and the *cos* DNA scaffold are limited to the N-terminal DBD of TerS, which forms a winged HTH domain (wHTH). This domain forms a dimer in solution with the helices of the HTH domain on the opposite protein surface to the dimerization interface (Fig. 6). While this model may not represent the natural oligomeric status in either the protomer or the tetrameric protomer assembly, it has proven to be a useful model system for analysis of λ TerS wHTH interaction with its cognate R2 or R3 DNA sequences. Residues on the recognition helix (helix 2) are proposed to form hydrogen bonds with base pairs in the major groove, while non-specific electrostatic contacts are likely made between the negatively charged phosphate backbone of the DNA and the positively charged amino acids on the N-terminal arm, wing and C-terminal end of helix 4 (Fig. 5B). Differences between the closely related λ and 21 phages can be used to infer the interactions that are crucial to genome selectivity. Within the 16 bp sequence of the conserved R motifs, two base positions determine packaging preference, where T7/C10 is bound specifically by λ TerS and G7/G10 is recognized by 21 TerS. However, precise mapping of the contacts requires more biophysical and structural experiments. Cleavage at *cosN* and release of the *cosQ* DNA end allows the reordering of the terminase proteins around the nascent end of the *cosB* DNA and the subsequent assembly of this motor-DNA complex to start the packaging process.

The mature packaged genomes of *E. coli* phage HK97 and related viruses (e.g., HK022) have complementary 10 base 3' ssDNA overhangs (3' GCGGCCGGTTT 5'), defined by a conserved *cos* sequence around the maturation cleavage site. While some proteins are predicted to share >90% amino acid (aa) similarity with λ phage proteins, no similarities are predicted in the terminase proteins. However, weak homology has been noted with the terminase proteins from the *Bacillus* phage phBC6A51 (40% aa similarity), the TerS of which forms a circular oligomeric complex (Fig. 6). Other than the fact that *cos* cleavage requires the terminase proteins (gp1 and gp2) and a virally encoded endonuclease containing an HNH motif (gp74), little is known about how the viral genome is recognized and the nascent ssDNA 3' overhang end is generated.

Genome recognition in headful bacteriophages

Bacteriophages that use the headful packaging system to pump slightly more than one genome length of the concatemeric DNA, result in the packaged DNA being circularly permuted, where the end of the genome that is packaged last overlaps somewhat into the adjacent genome copy, duplicating a short segment of the end of the genome that was packaged first. The iterative secondary transfer events after this initial 1+ packaging event cause the ends to the subsequently packaged genomes to migrate along the genome in the direction of packaging. This degeneracy in the genome composition relative to the ends of the packaged dsDNA is reflected in the variable requirement for sequence specific genome binding and initial cleavage precision used by different headful phages described below.

Since the *E. coli* T4 bacteriophage produces nuclease enzymes that degrade the host genomic DNA during viral replication, specific binding of the terminase proteins (gp16 and gp17) to a *pac* sequence appears to be less critical for packaging of the correct genome. Despite this, weak preferential binding has been observed between TerS (gp 16) and a GC rich sequence at the end of its coding region, subsequently denoted as the *pac* sequence (Fig. 5(C)). However, in the absence of this sequence, cleavage of the concatemeric DNA, prior to packaging, can occur at alternative terminase binding sites. T4 phage TerS forms single circular oligomeric assemblies of 11 monomers, while TerS from a related phage, 44RR, is found as oligomeric assemblies of 11 or 12 monomers (Fig. 6). Single T4 TerS rings may also stack, and two such rings can bind to different sites on the concatemeric T4 genomic DNA creating a 'synapse' that is thought to be important for terminase gene amplifications and packaging initiation. No DBD has been identified in these TerS proteins, and while the central oligomerisation domain does not bind to DNA, it is essential for genome packaging. This suggests a role for conformation recognition of genomic DNA. The T4 phage TerS oligomers support the stable assembly of higher order assemblies of TerL which exhibit enhanced ATPase activity. *In vivo*, genome end processing and packaging initiation of nascent concatemer DNA is coupled to genome replication and RNA transcription of the late genes required for viral survival. This occurs *via* the interaction of TerL with a large regulatory protein complex comprised of the DNA sliding clamp and two transcription cofactors (gp45/gp55/gp33), which assist in localizing the terminase complex to newly synthesized genomic DNA for end maturation (likely at the *pac* site in gp16) and subsequent packaging into the phage heads.

Selective packaging of the *Salmonella* phage P22 genome relies on sequence specific binding of the terminase proteins to the 22 bp *pac* sequence in order to direct the cleavage event that generates the free dsDNA end required for translocation of the genome into the capsid (Fig. 5(D)). A single cleavage event occurs most often close to the first base of the *pac* sequence. However, this initial cleavage event can also occur at any one of several positions, approximately spaced by 20 bp, within the 120 bp region spanning the *pac* site, suggesting that endonuclease activity is not directly sequence dependent. The P22 TerS protein (gp3) forms a circular assembly of 9 monomers (Fig. 6) that is known to associate with up to 3 TerL (gp2) monomers (Fig. 5(D)). The N-terminal domain of TerS does not form a classical HTH motif as it contains a β -hairpin insertion, however, the most similar structure to this domain is the DBD from the *Bacillus* phage SF6 TerS (Fig. 6), an HTH motif. The first two α -helices after the P22 TerS β -hairpin ($\alpha 3$ and $\alpha 4$) are in a similar orientation to the support and recognition helices ($\alpha 2$ and $\alpha 3$, respectively) of the SF6 HTH (Fig. 6). Indeed, mutations in P22 TerS amino acid residues, Leucine 80 and Glutamic acid 81, shown to alter *pac* specificity, map to helix $\alpha 4$ of the HTH-like motif, suggesting that this helix may also play a direct role in *pac* sequence recognition and binding (Fig. 5(D)). The flexible C-terminal segment of the TerS monomer is highly positively charged and can bind to the N-terminal domain of TerL to form the full Terminase complex (TerS₉:TerL₂₋₃). Although this C-terminal TerS segment can interact nonspecifically with DNA in the absence of TerL, stable formation of TerS-TerL complexes, both *in vivo* and *in vitro*, preclude the requirement of this interaction for specific recognition of the P22 viral genome. While a threading model for DNA interaction has been proposed, where the DNA passes through the central channel of the nonamer, the 120 bp cleavage zone around the *pac* site suggests a wrapping model reminiscent of the nucleosome core particle (Fig. 3(C)) and is consistent with the involvement of $\alpha 4$ in *pac* binding (Fig. 5(D)). Assuming a roughly B-form DNA conformation with regular bends, as in the nucleosome wrapped DNA, with the *pac* site centered within the bound DNA segment, evenly spaced sequences (where 20 bp is approximately equal to two turns of B-form DNA) would be presented facing outwards for cleavage by a TerL nuclease domain. This spacing, rather than the 10 bp of a single turn of B-form indicates that additional interactions between the DNA and TerS or TerL may stabilize the complex and occlude access to the DNA by TerL nuclease active site.

The packaging initiation endonuclease reaction of the *Shigella* phage Sf6 concatemer can happen at any one place over a 2000 bp range, centered around a 30 bp *pac* site identified in the TerS (gp1) gene (Fig. 5(E)). This sequence is recognized by the N-terminal HTH domains of the Sf6 TerS protein that are displayed externally around the central stabilising core of the circular octamer (Fig. 6), suggesting that both sequence specific and conformational recognition modes play a role in assembly of the TerS-*pac* DNA complex. While a *pac* sequence for preferential binding has been identified, Sf6 TerS shows high non-specific binding activity to both linear and supercoiled dsDNA, through positively charged residues located on the external surface of the circular array. The C-terminal domain of the DNA bound TerS assembly interacts with TerL (gp2) bringing the nuclease domain into close proximity to the DNA for the maturation cleavage event. Since cleavage can occur anywhere up to 1000 bp from the *pac* site in either direction, it is possible that once assembled on the *pac* sequence, the DNA wrapped TerS complex can slide randomly along the DNA, in a similar mechanism to nucleosome core particle sliding. A random sliding activity is consistent with the observation that the cleavage event takes place more often at *pac* proximal sites than at sites located at the extreme ends of the 2000 bp cleavage zone.

The concatemer DNA from the closely related *Bacillus* phages, SF6 and SPP1, is initially processed to produce DNA that is cleaved within a short 6bp segment of the *pacC* site to produce single base 3' overhangs (Fig. 5(F)). The 270 bp *pac* sequence is comprised of two main binding regions, *pacL* and *pacR*, on either side of the *pacC* site. The *pacL* sequence has a strong propensity

for bending and is bound by the nonameric TerS ring-like assembly through conformation recognition of the bent DNA assisted by weak sequence specific contacts. Nine HTH domains project a positively charged surface from the central oligomeric core (Fig. 6) that presumably allows the protein to form a complex with the DNA wrapped around it. Two TerS oligomers each bind to individual *pacL* and *pacR* sites placing the associated TerL nuclease domain so that it cleaves accurately at *pacC* regardless of the local nucleotide sequence at the cut site.

Atomic structures have been determined for TerS assemblies from understudied bacteriophage (*Thermus* phage G20c and *Bacillus* phBC65A1) where there is little information on the genome maturation and packaging processes. These proteins also form circular assemblies of 9 monomers that display classical HTH domains around the central oligomerisation domain (Fig. 6), however the mechanism of genome recognition and the packaging initiation cleavage event are yet to be defined.

DNA Wrapping/Bending is a Common Feature in Selective Packaging

Bacteriophages have long served as relatively simple model systems in which to study the fundamental mechanisms used by the macromolecular machines that act on nucleic acids. This longstanding focus towards understanding these processes has yet to yield much of the molecular detail of protein-nucleic acid complex assembly and function during packaging initiation. Conspicuous among these is the absence of atomic structural information of Terminase-DNA complexes. However, the puzzle pieces of information that are available for the different phage systems highlight some general features of the mechanisms for selective binding and packaging of cognate genomic DNA.

The N-terminal DBDs of TerS and $\phi 29$ TP are predicted to be α -helical. Indeed, many TerS DBDs form HTH or HTH-like motifs (Fig. 6(A)) supporting a model where sequence specific binding might occur through the placement of a recognition helix along the major groove of the dsDNA at the preferred sequence motif. However, the affinity of the sequence specific contacts between the cognate DNA targets and HTH motifs are generally weak, consistent with the observation that TerS proteins from many phage systems form circular oligomeric arrays of 8–11 monomers (Fig. 6(B)). Oligomeric assemblies of TerS have also been reported for other viruses (8 for T7 and 11 for T4). The positioning of the α -helical DBDs, displayed in a ring around a core oligomerisation domain, creates a ring of positive charges (Fig. 6(C)) around which the genomic DNA is wrapped. Additional non-sequence specific contacts between the DNA and TerL protein(s) bound to the TerS oligomer may act like DBDs, to assist in stabilising the ternary complex in some viruses, such as P22. Flexible positioning of the DBDs relative to the oligomeric core, and each other, provide a pliable DNA binding surface that can accommodate variation in the shape of the target DNA. Similar wrapping of negatively supercoiled DNA around the cylindrical connector protein has been proposed for initiation of $\phi 29$ packaging. This serves two purposes: providing a mechanism for recognizing the general topology of viral genomic DNA compared to host cell DNA (for both monomeric and concatemeric genome replication products); and in concatemeric DNA, allowing the circular oligomeric TerS to form a stable complex with the continuous strand of nascent genomic DNA and to present a more accessible bent strand as the substrate for the cleavage event required for packaging initiation.

Despite the variation in approaches used by different dsDNA bacteriophages to generate new copies of their genomes and to couple packaging to this replication process, specific genome binding and selective packaging generally combines both sequence specific and conformational recognition modes, along with the avidity afforded by multiple contacts between the protein subunits of the oligomeric terminase assembly and DNA. This commonality exploits the basic topological properties of phage genomic DNA that, along with the most powerful molecular motor known in nature, allow the DNA to be packed tightly into the capsid creating an efficient method for packaging and transferring these large viral genomes between host cells.

Glossary

Arginine finger A basic residue, most commonly an arginine, that works *in trans* during ATP hydrolysis within an oligomeric complex. In other words, the arginine finger of a subunit within a multimeric ATPase will participate in hydrolyzing the ATP bound in a neighboring subunit's active site.

ASCE A member of the Additional Strand Conserved Glutamate family of ATPases.

Concatemer A single DNA strand that contains multiple identical copies of a DNA sequence in series.

Power stroke The force-generating step of a motor.

Rossmann fold A highly conserved nucleotide binding motif which is composed of a β -sheet sandwiched between multiple α -helices.

Introduction

All viruses must encapsulate their genome into a capsid shell during the replication cycle. Many viruses use an ATPase motor to actively pump their DNA into the small volume inside the viral particle, strictly confining the genome. Viruses that use this method of maturation typically have large genomes and the ATPase motor overcomes the entropic and enthalpic penalties for encapsulating this large amount of genetic material. In many of these motor-driven viruses, the genome is packaged to very high density, often approaching a quasi-crystalline state. For example, the ~ 48 kb genome of phage lambda is ~ 16 μ m end-to-end, but is packaged into a head with a diameter of only ~ 60 nm. The motor needs to be extremely powerful in order to pump the genome against the internal pressure that builds during packaging, and also highly regulated to ensure complete and efficient encapsulation. Therefore, viral genome packaging motors are a particularly exciting model for understanding motor force-generation and regulation.

Genome packaging motors are found in many viruses that infect organisms from all three domains of life. This includes viruses as large as the giant mimiviruses to small viruses such as adeno-associated viruses. For many of these motors, the molecular mechanisms and even the identities of motor components remain unknown. Here, we will focus on the best-understood classes of viral genome packaging motors: the terminases and phi29-type motors. These motors catalyze genome packaging in tailed bacteriophage, as well as herpesviruses. Because phage are the most numerous biological entities, these motors likely perform the bulk of viral genome packaging on Earth. Terminases are also important drug targets for combating herpesvirus infections, further highlighting the importance of these motors.

Both terminase and phi29-type motors pump DNA through a dodecameric ring complex that sits at one of the five-fold vertices of the icosahedral shell. In terminase motors, this complex is called the 'portal', whereas it is called 'connector' in phi29-type motors. Not only does DNA enter through the portal ring during packaging, but it also exits through the same channel. The portal also serves as the binding site for the neck and tail proteins that assemble upon maturation of the virus particle. Numerous crystal structures of portal complexes from diverse phages reveal that these proteins share a common core structure. This indicates that all portals are evolutionarily related, despite low sequence homology in their primary sequence. The portal ring has a central channel that is just wide enough for double-stranded DNA to pass through. This finding has led to the proposal that the portal strips the incoming genome of any proteins bound to the DNA. Moreover, this tight channel is suggested to play a critical role in the packaging process itself, perhaps by acting as a one-way valve or even as a primary component of the force-generation step. In all examined cases, the dodecameric portal complex creates a symmetry mismatch with the capsid by replacing a pentameric coat protein complex at the five-fold vertex of the icosahedron. Whether this symmetry mismatch plays a functional role in packaging remains unknown, although recent work suggests a possible role in genome packaging termination.

Terminase and Phi29 Motors are Branches Within the ASCE Family of ATPases

Phi29 motors primarily consist of the connector assembly, ATPase motor, and a specialized prohead RNA molecule, known as 'pRNA' (Fig. 1). During packaging, the connector protein binds to the ATPase motor through interactions with the pRNA, and the motor translocates the DNA through the connector into the capsid. In terminase motors, the portal assembly binds to the ATPase subunit (the large terminase, or TerL) directly without pRNA. Terminase motors have an additional endonuclease domain, which is used to initiate and terminate packaging (discussed below). Despite the differences in motor assembly, both phi29 and terminase motors rely on a similar catalytic core to power DNA translocation: the ASCE ATPase fold.

Viral genome packaging motors are derived from the ASCE (additional strand conserved glutamate) division of ATPases. The ASCE division contains numerous superfamilies of ATPases, including widely studied AAA+ ATPases, ABC transporters, RecA, and

Fig. 1 CryoEM structure of the Phi29 Motor. Density from difference maps isolating the connector (green), pRNA (magenta) and ATPase (blue) were combined to visualize the DNA packaging motor in $\phi 29$. (A) Close-up view of the phi29 motor. (B) The motor is shown in the context of the entire prohead. The front half of the prohead density has been removed so all the motor components can be seen. This figure has been adapted with permission from Morais, M.C., Koti, J.S., Bowman, V.D., *et al.*, 2008. Defining molecular and domain boundaries in the bacteriophage $\phi 29$ DNA packaging motor. *Structure*, 16 (8), 1267–1274.

SF1/SF2 helicases (Fig. 2). ASCE ATPases are ancient machines that function across all cellular life, as well as many viruses. Although their molecular mechanisms and roles are remarkably diverse, ASCE ATPases usually function as multimers that convert the chemical energy of ATP into mechanical work. ASCE ATPases also generally use a similar ATP hydrolysis mechanism. Thus, studies of the packaging motor structure and mechanism have broad relevance towards understanding the general principles of molecular machines.

The ASCE nucleotide binding motif uses a Rossmann ' $\beta\alpha\beta$ ' fold which is comprised of a β -sheet sandwiched between multiple α -helices. Different clades within the ASCE tree may add variable elements to this base structure, however there are four features that are common to all ASCE ATPases: the Walker A and B motifs, a catalytic base that is usually a glutamate residue, and a *trans*-acting motif (Fig. 3). The Walker A motif (also known as the P-loop; consensus sequence [G/A]xxxGK[T/S]), is a nucleotide binding motif that forms hydrogen bonds with the ATP phosphates in the active site. The threonine/serine residue in the Walker A motif is critical, as it coordinates a metal ion, often a magnesium, for ATP hydrolysis. Downstream in the protein sequence, the Walker B motif (consensus sequence $\phi\phi\phi\phi$ [D/E]), further assists in binding this metal, which coordinates the β and γ phosphates of ATP. Immediately downstream of the Walker B motif, a glutamate residue acts as an essential catalytic base, activating water for nucleophilic attack on the γ -phosphate of ATP. (Often this 'catalytic glutamate' is included in the Walker B motif, which yields a consensus sequence $\phi\phi\phi\phi$ [D/E]E.) The fourth feature, a positively charged *trans*-acting element from a neighboring subunit (known as the arginine finger) interacts with the γ phosphate of ATP to stabilize the hydrolysis transition state. This *trans*-acting element also links nucleotide sensing and ATP hydrolysis between subunits, a necessity for regulating activity within oligomeric ATPases.

Terminase and phi29-like motors have numerous features that are similar, suggesting a relatively close phylogenetic relationship. Previous phylogenetic analysis classified the terminases and the phi29-type motors as disparate families within the ASCE division of ATPases. The phi29-type motors were placed within the HerA/FtsK family of dsDNA translocases and the terminases as an offshoot of RecA ATPases. This classification was based purely on sequence analysis and secondary structure prediction. However, recent structural and mechanistic discoveries led to the conclusion that terminase and phi29-type motors are much more closely related and are two distinct clades within the same family (Fig. 2). The ATPase subunits of phi29 and terminase motors have a core Rossmann fold with additional elements appended. For example, there is an additional α -helix and three antiparallel β -strands inserted between strand 2 and helix B of the core Rossmann fold, differentiating them from other ASCE ATPases. An N-terminal helix has also been added, where it packs atop helices A, B, and C of the core Rossmann fold. The phi29 ATPase domain also contains a short antiparallel β -strand inserted between helix D and β -strand 5. Additionally, terminase motors have a C-terminal nuclease domain, while phi29 motor proteins lack nuclease activity. This is not surprising, because the phi29 motor does not cleave DNA during packaging (see below for more details). Finally, the terminase motor has a three-helix bundle subdomain in between the core ATPase domain and the nuclease domain. We refer to this subdomain as the 'lid' because it caps the ATPase active site (others have referred to this substructure as a 'linker' domain or ATPase subdomain II). The three-helix bundle lid subdomain is distinguished from the four-helix bundle lid subdomains of AAA+ and STAND ATPases. It is unclear whether phi29 has a similar lid subdomain, as the protein used for crystallization only contained the core Rossmann fold of the ATPase.

In addition to similar ATPase domain structure, both terminase and phi29 proteins form oligomers when bound to the portal/connector. In the absence of the portal/connector proteins, the subunits of terminase and phi29 motors are generally monomeric. CryoEM and biochemical studies of the terminase motor show a pentameric assembly of subunits. However the oligomeric state of the phi29 motor remains contentious, as biochemical studies suggest a hexameric assembly.

Assembly of the oligomeric motor onto the portal/connector facilitates ATPase and packaging activity. Both terminase and phi29 motors use a *trans*-activated ATPase mechanism through an arginine finger motif, similar to most other ASCE ATPases. The

Fig. 2 Phylogenetic tree of ASCE ATPases. The core Rossmann fold is shown in green, while branch-specific structural features are shown in various colors. The terminases and phi29-type ATPase families likely evolved from AAA+ ATPases.

Fig. 3 The terminase ATPase active site. The P74-26 bacteriophage ATPase domain is shown. ADP-BeF₃, a non-hydrolyzable ATP analog, is bound in the active site. The Walker A motif hydrogen bonds with the ATP phosphates, and the conserved serine residue coordinates a magnesium ion (purple sphere). The Walker B motif further assists in binding the magnesium, with the catalytic glutamate coordinating a water (not shown) for nucleophilic attack.

arginine finger is positioned within the interface between two subunits, directly contacting the ATP γ -phosphate to stabilize the developing negative charge during the ATP hydrolysis transition state. In phi29, the arginine finger also causes ejection of ADP from the post-hydrolysis state. Thus, the arginine finger residue not only plays a catalytic role, but also ‘communicates’ nucleotide status between subunits within the ring. Because the arginine finger is central to motor function, its position on the protein surface dictates the relative orientation of neighboring subunits within the ring. In terminase and phi29 motors, the arginine finger is located in different regions of the protein, suggesting that the overall orientation of ATPase subunits may be altered between the two classes.

Phi29 and terminase motors are further distinguished by the accessory subunits required for efficient packaging. Terminase motors use the small terminase protein (TerS), which specifically recognizes the viral genome and modulates large terminase ATPase and nuclease activity. Phi29 lacks a clear homolog of TerS, and instead uses the gp3 protein which is covalently bound to the 5′ ends of the viral genome. The gp3-DNA complex is suspected to be the recognition element for packaging initiation. Additionally, phi29 uses the 174 base pair long pRNA for binding the motor to the connector. The pRNA forms a pentameric assembly on the connector, binding to the phi29 motor through a spoke-like RNA secondary structure. Terminase motors do not require a pRNA to bind portal, and bind through direct protein-protein interactions.

Phi29 Motors

The viral genome packaging machinery in phage phi29 is arguably the best understood system. The phi29 packaging motor was discovered in the 1970s and an *in vitro* packaging system was established in 1986. The ability to reconstitute genome packaging from purified components opened the door for years of incisive study. Furthermore, the phi29 motor chemomechanical cycle has been elucidated to high detail using an elegant single-molecule optical trapping assay for motor activity. Early optical trap experiments established phi29 as an exceptionally powerful motor, working against forces averaging 57 pN, a force close to that at which dsDNA fundamentally alters its conformation through over-stretching. Subsequent experiments identified individual subunit stepping, which provided incredible detail into the mechanisms of force generation. Finally, recent structural analysis has visualized a functioning holoenzyme at low resolution and various individual components at high resolution.

Phi29 genome replication and packaging begins with the gp3 protein. At the beginning of viral genome replication, gp3 covalently binds to the 3′ end of the genome, where it acts as a primer for replicating the 5′ strand. The gp3 priming domain dimensions and charge mimic DNA, allowing the polymerase to initiate replication by covalently linking a nucleotide to the hydroxyl of a serine within gp3. After DNA replication is complete, both ends of the DNA, known as left and right, remain bound to gp3. DNA-gp3 forms lariat loops, with the left end junction preferentially interacting with the packaging motor bound to the prohead. Binding to the motor causes DNA to supercoil, with some evidence suggesting that the supercoil wraps around the connector protein outside of the capsid. In an unknown mechanism, the motor begins packaging the gp3-DNA, possibly through packaging the loop in its entirety, or through gyrase activity that has been speculated but never directly observed, allowing the loop to resolve.

The translocation of the genome into the empty phi29 capsid occurs in a complicated, ATP-dependent mechanism. Each translocation cycle can be separated into two phases: a ‘burst’ phase in which DNA physically pushes into the capsid, and a ‘dwell’ phase in which the motor resets (Fig. 4). At the beginning of the ATP hydrolysis cycle, each subunit of the phi29 pentameric motor binds ATP. Once the ring is fully loaded with ATP, ATP hydrolysis is stimulated in a sequential order around the ring. During the burst phase, DNA is translocated by a total of 10 bp. By slowing the rate of translocation, Bustamante and colleagues showed that the 10 bp burst actually consists of four discrete 2.5 bp substeps. Thus, the pentameric phi29 motor uses 4 translocation events per cycle, which suggests that not every subunit directly translocates DNA per cycle.

One of the five motor subunits hydrolyzes ATP, but does not translocate DNA, and is designated the ‘special’ subunit. The exact role of the special subunit is still unclear; however, it is critical for regulating the motor during the dwell phase, which occurs in between each of the 10 bp translocation increments. It is thought that the special subunit grips DNA during the dwell phase, and releases ADP from its active site, allowing ATP to bind. The arginine finger of the special subunit and each subsequent subunit triggers ADP exchange for ATP sequentially within the ring, resulting in a fully ATP-loaded motor. The DNA-bound special subunit then initiates ATP hydrolysis, breaking its contact with DNA, and triggering the burst translocation phase. During the four subsequent ATP hydrolysis events, ATP is hydrolyzed and P_i released. P_i release induces the conformational change that drives the translocation step, packaging 2.5 bp of DNA before handing it to a neighboring subunit. Upon the power stroke conformational change, the arginine finger of the currently active subunit positions into the neighboring subunit’s active site, priming the next subunit for an ATP hydrolysis event. In this way, hydrolysis in the next subunit is triggered, and the DNA is processively packaged.

During the various packaging steps, DNA needs to undergo multiple ‘grip-and-release’ cycles. DNA is held by each subunit tightly during the translocation substeps as well as during the dwell; however, each subunit must relinquish its hold on DNA to easily pass off the DNA to a neighboring subunit within the ring. DNA is gripped mostly through the 5′-3′ strand, with less contact made with the 3′-5′ strand and minor contacts with sugars and nucleotide bases. Upon passing to the next subunit during translocation, the DNA undergoes rotation. As sequential hydrolysis and DNA translocation occurs during the packaging reaction, translocation step size and DNA rotation per cycle starts to vary. As more DNA is encapsulated, the step decreases from 2.5 to 2.3 bp, and the rotation of DNA increases from -14° to -48° per increment. This is in accord with increased packaging density within the capsid and subsequent elevated backpressure, which the motor must work harder against in order to continue the

Fig. 4 The Phi29 chemomechanical ATPase cycle. At the end of the burst, all subunits are ADP-bound (“D” label). At the beginning of the dwell, the motor makes an electrostatic contact with two backbone phosphates (small red circles) on the dsDNA substrate (inside the ATPase ring). This unique contact determines the identity of the special subunit (yellow label “s”). The formation of the electrostatic contact facilitates ADP release by the special subunit. Subsequent ATP (“T” label) binding and ADP release events are interlaced, with ATP binding to one subunit enabling ADP release from its neighbor. After all five subunits have bound ATP, the special subunit hydrolyzes ATP (“D•Pi” label), releases Pi, and uses the hydrolysis free-energy to break the electrostatic contact with DNA, triggering the burst phase. During the burst, the remaining four ATP-bound subunits sequentially hydrolyze ATP, release Pi, and translocate DNA by 2.5 bp. The motor-DNA geometry (10.0 bp burst size versus 10.4 bp dsDNA helical pitch) favors a mechanism in which the same subunit is special in consecutive cycles. This figure is reprinted with permission from Chistol, G., Liu, S., Hetherington, C.L., *et al.*, 2012. High degree of coordination and division of labor among subunits in a homomeric ring ATPase. *Cell* 151 (5), 1017–1028.

packaging reaction. Recent work has shown that this backpressure can be relieved by a temporary pause in packaging, which allows the DNA to relax in the capsid. Because this relaxation time is far longer than the packaging time, this result suggests that the fast speed of packaging causes DNA to adopt a metastable conformation. These findings illustrate that motor speed has an important role in determining capsid internal pressure and genome dynamics.

The structure of the phi29 motor is beginning to come into focus. The connector assembly structure was first determined to high resolution by x-ray crystallography, along with a low-resolution cryoEM structure of the motor actively packaging. Subsequent cryoEM studies show that the portal undergoes large conformational changes in structure upon packaging and suggest a pentameric arrangement of the pRNA and ATPase components of the motor. The pentameric arrangement has been challenged, with the more commonly seen hexameric ATPase arrangement proposed. However, high-resolution asymmetric reconstructions of the phi29 motor structure exhibit a clear five-fold or pseudo-five-fold arrangement of subunits. Over the past decade, high-resolution structures of most of the motor components have been determined: a majority of the pRNA structure was determined by crystallography and NMR, as well as the ATPase domain of the gp16 motor protein. By docking the high-resolution structures into the cryoEM density, we are nearing a complete picture of the phi29 motor. High-resolution structures of the motor in action are still needed to understand the motor’s mechanism in detail. However, the rapidly developing field of cryoEM is nearly certain to profoundly impact our understanding of the phi29 motor in the future.

Terminase Motors

In comparison to phi29 motors, less is known about terminase motor mechanism. Because terminases have been studied from multiple phages, here we synthesize the results from many model systems, such as phages T4, lambda, SPP1, P22, Sf6, and P74–26. Terminases initiate genome packaging using the small terminase protein. The small terminase binds to the viral genome and modifies the enzymatic activities of the large terminase protein. In some cases, such as found in phage lambda, host factors augment the small terminase’s role as a regulator of large terminase function. Additionally, terminase activity is modulated by the procapsid, which is required for terminase translocation. Other factors have been proposed to regulate terminase functions, such as the gpFI protein of phage lambda. However, more recent evidence suggests that regulation by gpFI is either unnecessary for phage replication or does not occur *in vitro*. Terminases are also controlled at the level of protein translation, as the terminase protein is often expressed late in the infection cycle. Finally, large terminase genes often contain self-splicing intein sequences in their ATPase active sites that are hypothesized to modulate terminase activity.

Terminase motors translocate DNA at a faster rate than their phi29 counterpart, with the T4 motor taking 5–10 min to package its 171 kb genome. While terminases are faster translocases, they exhibit more variable speed. *In vitro*, the T4 motor translocates DNA at an average rate of 700 bp/s, peaking at 2000 bp/s with an ATP turnover rate of 300/s. The terminase of phage lambda peaks at ~600 bp/s at low capsid density, but this rate drops to ~200 bp/s towards the end of packaging. Meanwhile, phi29 packaging peaks at around 165 bp/s *in vitro*, making it significantly slower. Therefore, the motor speed seems to be correlated with

Fig. 5 Proposed ‘inchworm’ model for the mechanism of DNA translocation by the large terminase. Panels (A)–(D) relate to the sequence of events that occur in a single large terminase molecule. The large terminase N-terminal subdomain I, subdomain II, and C-terminal domain are represented as green, yellow, and cyan ovals, respectively. The five-pointed stars show the charge interactions between the N-terminal subdomain I and the C-terminal domain. The four-pointed stars show the charge interaction between the N-terminal subdomain II and the C-terminal domain. The flexible linker between N- and C-terminal domain is represented by a wiggly cyan line. (A) The large terminase C-terminal domain is ready to bind DNA. (B) The C-terminal domain, when bound to the DNA, brings the DNA closer to the N-terminal domain of the same subunit. Conformational change in the N-terminal domain causes Arg162 to be placed into the ATPase active center in preparation for hydrolysis. (C) Hydrolysis of ATP has rotated the N-terminal subdomain II by about 6° , thereby aligning the charge pairs resulting in an electrostatic attraction that moves the C-terminal domain and the DNA 6.8 Å (equivalent to the distance between two base pairs) closer to the N-terminal domain and into the capsid. (D) ADP and P_i are released and the C-terminal domain returns to its original position. DNA is released and is aligned to bind the C-terminal domain of the neighboring subunit. This figure is adapted with permission from Sun, S., Kondabagil, K., Draper, B., *et al.*, 2008. The structure of the phage T4 DNA packaging motor suggests a mechanism dependent on electrostatic forces. *Cell* 135 (7), 1251–1262.

genome size: faster motors are found in phages with larger genomes such that the total packaging time is similar across multiple phages. In comparison to other ASCE ATPases, the T4 large terminase moves along DNA considerably quicker than the fastest known helicase RecBCD, which unwinds DNA at a rate of ~ 1000 bp/s. However, it is slower than the FtsK and SpoIIIE dsDNA translocases, which move at a rate of 5–17 kb/s and ~ 4 kb/s respectively.

The speed of the motor coupled with increased forces inside the capsid during packaging requires an incredibly powerful ATPase to complete the packaging reaction. It is estimated that the power density of the T4 motor is approximately 5000 kW/m^3 , which is twice that of a typical automobile engine. How terminases generate this tremendous power is one of the central questions that has been debated within the field for decades, and several models for terminase mechanism have been proposed to explain this phenomenon (see below).

Terminases are generally composed of an N-terminal ATPase domain and a C-terminal nuclease domain. The two domains are connected by a short linker, allowing for some degree of flexibility between the two halves of the protein. In addition to the ASCE ATPase family features listed in the above section, the large terminase ATPase domain contains a subdomain known as the ‘lid subdomain’ immediately upstream of the linker. The lid subdomain forms the upper portion of the nucleotide binding pocket, and is essential for ATPase activity (Fig. 3). In related AAA+ proteins, the lid plays an important role in propagating nucleotide-dependent conformational changes to adjacent subunits within the ring.

Although the mechanism of translocation in terminases remains unknown, many models have been proposed. Some of these models have been proven incorrect. For example, an early hypothesis that the portal ring rotates within the capsid to drive translocation has been disproven by observations that the portal does not rotate during packaging or in the mature virion. Here we examine several of the current leading models in detail.

The “Inchworm” Translocation Model

One of the primary models for DNA translocation by terminases is an “inchworm” model in which DNA is pulled into the capsid via a spring-like motion (Fig. 5). This model was originally derived from biochemical and structural analysis of the T4 phage large terminase protein, including high-resolution crystal structures of the T4-TerL protein, and a low-resolution cryoEM structure of the T4 procapsid bound to TerL. A modified version of the inchworm hypothesis was proposed later from high-resolution crystal structures of Sf6 phage large terminase. In this model, the ATPase domains bind to the capsid and portal while the nuclease domains grip DNA in the center of the pore. In the inchworm mechanism, a key catalytic residue (Arg162) is repositioned into the active conformation from both DNA binding to the nuclease domain and ATP binding to the active site in the core ATPase domain (Fig. 5(A) and (B)). This induces ATP hydrolysis, which in turn is predicted to rotate the lid (also known as subdomain II) by $\sim 6^\circ$ and move the short flexible linker region between the ATPase and nuclease domains by about 3 Å (Fig. 5(C)). This conformational change is proposed to align a set of ion pairs between the ATPase and the nuclease domains, resulting in a stronger electrostatic attractive force between the two domains. The electrostatic interactions pull the domains towards each other, and this ‘relaxed’ to ‘tensed’ conformational change translocates 2 base pairs of DNA upward into the capsid. During the reset phase of translocation, ADP and/or P_i release from the active site reorganizes the terminase subunit back into the relaxed state via the loss of negative charges from ADP and P_i release (Fig. 5(D)). ATPase subdomain II rotates back, attenuating the electrostatic force between the

Fig. 6 Proposed ‘lever’ model for the mechanism of DNA translocation by the large terminase. (A) Large terminase ring is shown. The nuclease domains interact with the portal complex (translucent gray rectangle) and possibly the procapsid (black curve). DNA is not shown but interacts with the large terminase through the DNA interaction motif. Each subunit’s lid is bound tightly to the Rossmann fold of the adjacent subunit. (B) Upon ATP hydrolysis and release by the magenta subunit, the lid stays bound to the blue subunit and the Rossmann fold rotates 13° upward. To allow for this movement, the adjacent red subunit must also move in concert with the magenta subunit. To represent that the second site of symmetry breaking is unknown, the other three ATPase domains are faded. After hydrolyzing ATP, the magenta subunit releases DNA to the red subunit to translocate DNA upward through the pore; into the pore of the portal complex; and, ultimately, inside the procapsid. The release of DNA at each cycle by the ATP-hydrolyzing subunit allows for unidirectional DNA translocation. This figure is reprinted with permission from Hilbert, B.J., Hayes, J.A., Stone, N.P., *et al.*, 2015. Structure and mechanism of the ATPase that powers viral genome packaging. *Proceedings of the National Academy of Sciences of the United States of America* 112 (29), E3792–E3799.

ATPase and nuclease domains. The nuclease domain releases its grip on DNA, which is presumably passed to a neighboring subunit preceding or during the release of ADP and/or P_i .

While this model paints a comprehensive picture of the terminase packaging reaction, the proposed mechanism does not explain several observations. First, previous studies found the motor binds the portal in the reverse orientation, with the nuclease domains contacting the portal rather than the ATPase domains. Second, with the ATPase domains splayed radially from each other and bound to portal, the *trans*-activation mechanism required for ringed ASCE ATPase activity cannot occur. Third, the regions predicted to mediate interactions with DNA show particularly low conservation and are only found in T4-like phage. Finally, the observed conformational changes do not fully explain DNA translocation. The small changes in conformation do not match a ~2 bp step size that has been predicted for terminases. No significant conformational changes were observed in the structures of T4-TerL. This may be due to crystal contacts within the active site or the mutation of Walker B motif in the crystallization constructs. Moreover, there is a discrepancy in the Sf6 structures wherein the ATP γ S structure, which should be locked in a ‘ATP-like state’ is identical to the ADP-bound and apo states. This may be due to the fact that the Sf6 TerL was crystallized in the apo state, and then nucleotide ligands were soaked into the pre-assembled crystals. In many cases, the crystal lattice in the apo state does not allow for a ligand-induced conformational change in soaked crystals.

The “Lever” Translocation Model

Another model for viral motor DNA translocation is the lever model (Fig. 6). In this model, a lever-like conformational change in the ATPase domain driven by ATP hydrolysis forms the power stroke of DNA translocation. In contrast to the aforementioned “inchworm” model, the “lever” model positions the ATPase domains as the central hub of the ring, while the nuclease domains protrude radially and attach to portal and capsid. Evidence of this assembly model comes from several crystal structures, molecular docking, and various biochemical analysis to determine the critical residues for motor function.

The identification of a *trans*-acting arginine finger was a critical step in developing the lever model. Identifying this residue led to reinterpretation of the “inchworm” structural model in which the ATPase domains do not contact neighboring subunits. The “lever” model places the ATPase domains into a ring to facilitate *trans*-activated ATP hydrolysis, placing the nuclease domains in contact with portal. Further unbiased pentamer docking experiments of a monomeric crystal structure of the P74–26 ATPase domain positions the predicted arginine fingers precisely for *trans*-activated ATP hydrolysis, providing a second layer of evidence for the inverted structural model. Interestingly, the pentameric model also fits well into the T4 packaging motor electron density map, indicating its potential biological relevance.

Furthermore, the pore of the pentameric docked model is lined with several conserved basic residues, indicating a role in DNA binding. Mutating these residues abrogates TerL binding to DNA. Interestingly, mutation of residues in the nuclease domain has no substantial effect on DNA binding affinity. In fact, the TerL ATPase domain can bind DNA with nearly the same affinity as full-length TerL. Assimilating these findings with the structural model yields a mechanistic model where the ATPase domains grip and translocate DNA in the central pore of the ring, while the nuclease domains bind to the portal and do not interact with the DNA during packaging (Fig. 6(A)).

The lever model predicts that DNA is translocated by a lever-like motion of the ATPase domain while gripping to DNA. These motions were identified by comparing crystal structures of P74–26 phage TerL, which shows significant conformational changes in the apo state or bound to a non-hydrolyzable ATP analog. Comparing the apo and ATP analog bound states, the lid subdomain undergoes a 13° rigid-body rotation. Because modeling and mutational analysis suggests that the lid subdomain forms the primary interaction surface between adjacent ATPase domains, this rotation has a substantial effect on the conformation of the ring. With the lid subdomain stabilized through neighboring contacts, the 13° rotation is transmitted to the Rossmann fold, which is the large domain of the ATPase module. This results in a lever-like movement of the ATPase domain (Fig. 6(B)). This movement is calculated to shift the DNA binding region 8 Å upward towards the capsid and rotate DNA an estimated 2.3°. This is very similar to the 2.5 bp DNA translocation step measured in phi29 motors. It is predicted that upon either P_i or ADP release, the gripping subunit loses affinity for DNA and passes it off to the adjacent subunit. The adjacent subunit will now grip DNA tightly because it is in an ATP-bound state, which has been shown to have the highest affinity for DNA. This handoff would then allow the subunit that hydrolyzed ATP to release ADP and P_i so that it can bind ATP, thereby resetting for the next cycle. By acting in concert with two subunits simultaneously, the DNA can be translocated efficiently. Moreover, the motor produces very high force because the lever arm (the entire Rossmann fold) is quite long.

The DNA “Crunching” or “Compression” Translocation Model

A third DNA packaging model is the DNA “crunching” or “compression” model (Fig. 7). In this mechanistic model, the motor uses ‘torsion’ caused by DNA compression inside the terminase assembly to propel DNA into the capsid. In other words, the DNA itself plays an active role in the force generation process. Specifically, with the motor attached to portal and DNA bound in the center, both portal and the terminase subunits grip the DNA and hydrolyze ATP (Fig. 7(A)). ATP catalysis leads to a brief DNA compression which disrupts the B-form DNA structure, transiently adopting A-form DNA in what is referred to as a “crunched” state (Fig. 7(B)). The return of this compressed state into the B-form state is assumed to cause the DNA translocation power stroke during the packaging cycle (Fig. 7(C)). Evidence for this mechanism lies in several observations. A FRET experiment using a double-labeled fluorescent Y-DNA designed to stall the T4 packaging motor estimated 22%–24% DNA compression within the terminase motor when packaging was stalled. Additionally, subsequent packaging experiments using an intercalating dye, YOYO-1, showed dye release from the DNA during the packaging reaction. This observation is attributed to DNA compression inside the motor, as covalently attached DNA-binding labels are more readily packaged. Observations that the motor does not readily package RNA-DNA hybrids also suggest this mechanism, as RNA-DNA hybrid complexes assume a mostly A-form structure and therefore are not compressible, preventing the scrunched to relaxed transition from driving the translocation power stroke. Two slightly different variants on the scrunching model have been proposed, with one model hypothesizing that the scrunching occurs within the terminase central pore, while the other model hypothesizing that the compression occurs within the portal channel. We note that the compression model is not mutually exclusive with either of the two other models we discuss here; it is possible that force generation is through a combination of the compression model and either the inchworm or lever models.

Termination of Packaging

Phi29 and related bacteriophages replicate their genome as monomers rather than concatemers as most phages do. Thus, packaging is terminated when the entirety of the DNA strand is packaged and no DNA cleavage is required. A 16 Å resolution cryoEM structure of a mature phi29 viral particle shows the DNA packaged inside the prohead with density in the channel of the connector and within the tailtube, both of which were assigned to the right-end gp3. A second cryoEM structure of fiberless phi29 particles at 7.8 Å resolution confirmed the presence of gp3 within the tailtube, indicating that the right-end gp3 does not get fully packaged, while the connector-tailtube channel contains DNA bent in a toroid-like structure. This novel 60 Å-in-diameter highly-bent DNA structure appears to be the result of DNA under extreme pressure. While the function of the toroid structure is unknown, the authors speculate it plays a role in holding the DNA inside the tail during infection. Further studies are necessary to explore this idea.

Fig. 7 Phage DNA packaging via a torsional compression mechanism. (A) A fully assembled packaging complex is shown, with the empty prohead (red) carrying the portal ring (blue) shown at one vertex, and the DNA duplex drawn in black. Only two subunits of the large terminase (orange) are shown for clarity. The terminase subunits are sketched with a minor lobe, representing a flexible region that undergoes a conformational change (black dashed arrow) coupled with ATP binding and hydrolysis (white solid arrow). The exact steps and temporal order by which the binding and hydrolysis of ATP is coupled to movement of the large terminase during the reaction cycle is not specified. (B) Directed linear motion of the flexible arm of the large terminase subunit engages the DNA substrate and translocates this towards the prohead. This movement coupled with interaction of the DNA with the portal region causes induced changes to the helical pitch and temporarily stores energy. (C) The stored energy is released by translocation into the prohead (green arrow), restoring the B-form helical repeat. This figure is adapted with permission from Oram, M., Sabanayagam, C., Black, L.W., 2008. Modulation of the packaging reaction of bacteriophage t4 terminase by DNA structure. *Journal of Molecular Biology* 381 (1), 61–72.

Terminases package concatemeric genomes and therefore must cut the DNA at the end of packaging. For viruses in this class, the genomes are typically synthesized by rolling circle DNA replication, resulting in multiple copies of the genome linked in a series (*i.e.*, concatemers). Packaging is accomplished in one of two ways. In the first mechanism, typified by the lambda phage, the terminase cuts a specific site in the genome, resulting in exactly one genome length being packaged into the head (referred to here as ‘unit-length packaging’). In the second mechanism (known as ‘headful packaging’), the volume of packaged DNA triggers the nuclease cleavage mechanism, rather than a specific DNA sequence. The result of a headful packaging mechanism is that each capsid is filled with slightly more than one genome of DNA, creating terminally redundant ends that can be circularly permuted.

For ‘unit-length’ bacteriophage such as lambda phage, the motor nuclease domain cuts at a specific sequence, known as *cosN* in lambda phage. Nicks are made on either side of the DNA strand, leaving a 5′ twelve nucleotide overhang. For the initial cleavage event, a complex with the small terminase protein (gpNu1) and the *E. coli* protein Integration Host Factor (IHF) increase specificity and affinity for the large terminase to the *cosN* site. IHF bends the DNA nearly 180°, positioning two gpNu1 binding sites adjacent to each and presumably facilitating gpNu1 DNA binding, which in turn promotes large terminase nicking at *cosN*. During termination, an upstream site, *cosQ*, and a downstream site, *I2*, are necessary for accurate nicking, and mutations in *cosQ* lead to aberrant termination and formation of particles with uncut DNA protruding from the head. It is proposed that *cosQ* plays a role in properly positioning the terminase/nuclease domains for antiparallel DNA cleavage at the *cosN* site, and that the volume of packaged DNA may trigger its recognition.

In comparison to 'unit-length' packaging bacteriophage, 'headful' bacteriophage do not terminate packaging at specific DNA sequences; instead, termination is determined by the volume of the head. Because headful phages generally package slightly more than one genome into the capsid, the genome is terminally redundant for circular permutation. This process can result in the phenomenon of generalized transduction, in which phages can carry segments of bacterial genome from one cell to another. There are several strategies for headful packaging. For example, phage P22 cleaves after ~2%–10% of the next genome in the concatemer, which results in the next packaging cycle starting with a region downstream from the initial packaging recognition sequence. Other cleavage strategies are seen across different phage, suggesting that termination (and initiation) are controlled idiosyncratically by different phage.

Headful terminases must trigger nuclease activity through a mechanism that senses how full the capsid is. One hypothesis for how this is accomplished relies on the conformational state of the portal protein. In a recent study of the P22 portal ring, the authors found that during packaging the portal adopts an asymmetric assembly that binds tightly to the terminase motor (it is of note that the discovery of this asymmetric state also addressed how a pentameric motor could bind a dodecameric portal, a question that has eluded the field for several decades). However, once the head nears complete fullness, DNA binds around the capsid-enclosed portion of portal. DNA binding in this region triggers the asymmetric portal assembly to adopt a symmetric ring, thus losing affinity for the pentameric motor and presumably discharging it from the capsid head. After portal releases the motor, the motor nuclease domains cleave DNA, severing the packaged DNA from the rest of the concatemer, and terminating the packaging reaction.

Headful packaging mechanisms necessitate strict control to prevent premature cleavage of DNA. The small terminase subunit may play a regulatory role in this process, as it suppresses large terminase nuclease activity (while increasing ATPase activity). How this mechanism works is unclear, and the role of the small terminase during DNA translocation has yet to be fully resolved.

One model of DNA cleavage relies on separate DNA 'binding' and 'cleavage' interfaces of the nuclease domain. Terminases have nuclease domains of the RuvC/RNase-H family that use three acidic active site residues to coordinate two divalent metals (either Mg^{2+} or Mn^{2+}) to catalyze the cleavage reaction. Crystal structures of the T4 nuclease domain show a patch of basic residues far from the active site that are presumed to make electrostatic contacts with the DNA backbone during 'translocation mode'. Once endonuclease activity is triggered, the DNA is transferred through an unknown mechanism to the nuclease active site for cleavage. This putative DNA translocation interface is proposed to regulate the endonuclease activity by holding DNA away from the active site during translocation. However, it was later noted that no positively charged residues from this region are conserved throughout other bacteriophage nuclease domains, and that the nuclease domain has very poor affinity for DNA.

Further structural studies attempt to explain nuclease regulation through nuclease domain conformational changes. Analysis of the SPP1 bacteriophage nuclease domain crystal structure predicts that a conserved extended β -hairpin clashes with DNA bound in an RNase-H-like conformation, and that the loop must reorient upon DNA binding. Heterogeneity of loop positioning in different bacteriophage species and normal mode analysis calculations support this idea, suggesting that loop flexibility may limit active site accessibility for DNA, and thus acts as a nuclease regulation mechanism. Later studies using thermophilic terminases suggest that movement of this loop is not required if the terminase uses a different DNA binding mode. It was suggested that the nuclease domain cleaves DNA in a fashion similar to the thermophilic RuvC resolvase rather than RNaseH. In this model, the β -hairpin and residues surrounding the active site cradle DNA within a groove, positioning it in a desirable conformation for cleavage.

Another suggested mechanism of cleavage regulation is that DNA packaging occurs too quickly for nucleolytic activity to take place. While this is formally possible, motor stalls for extended time periods (seconds to hours) do not result in DNA cleavage, indicating this 'kinetic competition' model is not a primary mechanism for nuclease regulation.

Recently, the 'steric hindrance model' was proposed to explain regulation of terminase nucleolytic activity (Fig. 8). In this mechanism, the nuclease domains bind to portal and capsid during packaging, preventing the nuclease active site from engaging with DNA. Evidence suggests that the ATPase domains are solely responsible for gripping DNA, while the nuclease domains have no measurable affinity, supporting this arrangement. After ejection from portal, two nuclease domains bind and cleave DNA in an antiparallel arrangement, forming a double-stranded break. This rearrangement of the nuclease domains is made possible by a flexible linker connecting to the ATPase domain, allowing the nuclease domains to adopt the correct orientation for DNA cleavage. Once the DNA strands are cleaved, the tail proteins assemble on portal to create a mature virion.

Once packaging is finished, the motor must be replaced with the virus neck and tail. It is not clear how the DNA does not get prematurely released during the transfer of motor for tail. Various mechanisms for maintaining the pressurized DNA have been proposed. For example, the portal could act as a one-way valve. Additionally, the conformation of the DNA itself may help maintain packaged genome. Cryo-electron microscopy studies show the DNA tightly spooled in the capsid, typically with the central axis of the spool coincident with the long axis of the tail. The arrangement of DNA appears to be most homogenous at the periphery of the shell where the genome contacts the capsid directly, with the 'layers' of DNA becoming progressively more heterogeneous towards the center. DNA is often found to be ordered in the portal complex and even within the tail, as if it were locked down but poised for ejection. Typically, the DNA sequence that enters the head first is the last to leave the head upon infection, suggesting a simple unidirectional model for spooling of DNA in the head (T4-like phage are an exception; the first sequence in during packaging is the first sequence out during infection). Moreover, there are often proteins that also reside in or nearby this channel that are ejected soon after infection; these 'ejection proteins' presumably play an important role in early stages of infection, including the process of crossing the periplasm. It remains a mystery whether these proteins hold DNA in the capsid until infection or the motor plays a role in packaging these ejection proteins inside the capsid.

Fig. 8 Proposed 'steric hindrance' model for nuclease regulation. During 'translocation mode' the nuclease domain active site is sequestered from DNA by interactions of the large terminase with portal and capsid, preventing premature cleavage. The ATPase domain serves as the sole surface for gripping DNA during packaging. Upon completion of packaging the large terminase enters 'cleavage mode'. The large terminase loosens its attachment to the portal and capsid, releasing the inhibition of the nuclease domains. The ATPase domains remain tightly bound to DNA. The nuclease domains rearrange to cleave each of the antiparallel DNA strands. Although depicted as a blunt cut, cleavage could also leave overhangs depending on how both nuclease domains engage DNA. This figure is reprinted with permission from Hilbert, B.J., Hayes, J.H., Stone, N.P., Xu, R.-G., Kelch, B.A., 2017. The large terminase DNA packaging motor grips DNA with its ATPase domain for cleavage by the flexible nuclease domain. *Nucleic Acids Research* 45 (6), 3591–3605.

Outlook and Future Studies

Despite decades of research, there remain numerous questions as to how viral genome packaging motors processively translocate DNA. High-resolution structures of actively packaging motors are necessary to elucidate the DNA translocation mechanism. Visualizing the conformational transitions, intersubunit interactions, and DNA gripping contacts will shed light on how the motor generates the power to package DNA against the immense back pressure in the capsid. Structures of both phi29 and terminase motors will determine their similarities and differences, as well as address how force is generated.

While phi29 genome packaging has been investigated to fine detail, less is known about the terminase motor DNA translocation cycle. For instance, do terminases also hydrolyze ATP in a sequential order? Do they follow a similar chemomechanical cycle? Given that there are considerable differences in DNA translocation speeds of phi29 and terminases, it is possible that the two types of motors use different regulation strategies. Furthermore, it appears that the *trans*-acting arginine finger is different in terminases and phi29 motors. If so, how do two proteins with similar ATPase domain topologies employ different mechanisms? Having a clearer understanding of the terminase DNA translocation cycle will provide insight into these questions.

There are also many unknown regulation steps within the endonuclease reaction catalyzed by terminases. For example, how the motor senses when to cleave for both headful and unit-length filling mechanisms is unknown. For headful terminases, the portal has been implicated as a sensor, but whether the large terminase plays an active sensing role is still inconclusive. In unit-length bacteriophage such as lambda, the initial cleavage event has been elucidated in great detail, but how the termination cleavage occurs in the absence of gpNu1 and IHF is less clear. Some evidence supports the idea that lambda may use a headful-like sensing mechanism to trigger *cosN* cleavage, but whether this is regulated by the portal, the terminase itself, or the rate of DNA translocation at the end of packaging is undetermined. Finally, once the motor is released from portal, what prevents the genome from immediately ejecting from the capsid before the pre-assembled tail binds? Answering these questions will undoubtedly require synthesizing structural studies with careful biochemical and single-molecule assays.

Moving forward, the study of motor structure and mechanism will likely lead to new biotechnological applications. For example, the prNA of phi29 has already been used as a therapeutic delivery device. Are there applications for the motor itself? One could imagine

roles in nanomaterials and targeted delivery of biological cargo. As an example, the portal was recently engineered as a nanopore for sensing various biomolecules. Future studies of the motor may lead to a plethora of applications in biotechnology.

Glossary

ASCE The additional strand, conserved E (glutamate) superfamily of ATPases. A classification of proteins based on sequence, structure, and function. Terminases and other viral DNA packaging ATPases are members of this superfamily.

ATPase A protein that catalyzes ATP hydrolysis.

Procapsid The viral capsid prior to complete maturation of the virion.

Terminase A viral protein which packages DNA and performs endonuclease activity.

Introduction

A crucial step in virus assembly is the encapsulation of viral genome into the procapsid. Different viruses have evolved different strategies by which they package their genome. In many double-stranded DNA (dsDNA) viruses, such as some families of bacteriophages, DNA packaging is accomplished by packaging ATPases, powerful molecular motors that convert energy from ATP hydrolysis into mechanical work. This energy from ATP hydrolysis is used to overcome large internal forces arising from electrostatic self-repulsion, entropy loss, and DNA bending rigidity, which oppose DNA confinement within the capsid.

The packaging ATPase is a dimer of homo-oligomeric rings. One ring is comprised of large packaging proteins, and the second ring is comprised of small packaging proteins. The small packaging complex is responsible for recognizing the viral genome at a sequence-specific “pac site” to ensure that the virus only packages its own genome and not stray genome from the host bacteria. In some cases, such as the $\phi 29$ phage, the small packaging proteins are covalently attached to the end of the viral DNA, and recognition is attained via the assembly of the large and small packaging complexes. The large packaging motor protein is responsible for the ATPase activity which provides the necessary energy to translocate the genome into the viral procapsid. The packaging motors have evolved various mechanisms for initiating packaging, translocating DNA, and terminating packaging. The mechanisms involved in DNA translocation are especially elaborate, where mechanical actions such as DNA gripping and un-gripping (and/or steric pushing of the DNA), force generation, and coordination of the multiple motor subunits must be coupled to the ATP binding, bond cleavage, and product release steps of the ATP-hydrolysis cycle.

While there is currently no unified model that explains all aspects of DNA packaging for all phages, our understanding of packaging ATPases, especially their molecular structure, packaging characteristics, and packaging mechanism, has improved significantly through knowledge primarily gained from the three well-studied systems of the $\phi 29$, T4, and λ phages, which will mainly be highlighted here.

Molecular Structure

Viral DNA packaging proteins are members of the Additional Strand, Conserved Glutamate (ASCE) superfamily of ATPases, and are related to other ASCE ATPases such as ATP Binding Cassette (ABC) and ATPases Associated with diverse cellular Activities (AAA+) proteins. ASCE ATPases contain a conserved P-loop/Walker A (WA) motif involved in binding ATP, and a Walker B (WB) motif which helps catalyze ATP hydrolysis. Based on mechanisms deduced for other ATPases, catalysis is thought to be specifically dependent on a conserved glutamate residue located immediately downstream of the WB motif. Many packaging proteins also have endonuclease activity necessary to initiate and terminate the packaging process in the case where viral DNA replication results in catenated strings of multiple genomes; As such, these proteins are called “terminases”. Terminases have two distinct domains: the ATPase and nuclease domains, which are connected by a flexible linker. The T4 and λ phages use terminase proteins. The $\phi 29$ motor does not perform endonuclease activity and its motor enzymes are referred to by the more general term “packaging ATPase.”

The molecular structures of the monomer subunits from several packaging ATPases have been solved either in part or in whole via X-ray crystallography. The first near-complete monomer structure to be solved was from the T4 phage in 2008, followed by those from the Sf6 and D6E phages in 2013 and 2017. The structures of the ATPase domain of the P74-26 phage terminase protein and a partial ATPase from the $\phi 29$ phage were also solved, and so have the structures of the nuclease domains of the P74-26, SPP1, P22, G20c, and RB49 phage terminase proteins. There is significant structural homology across all of the ATPase and nuclease domains, although the relative positioning of the nuclease domain with respect to the ATPase domain is drastically different in the solved T4, Sf6, and D6E terminase structures (Fig. 1). The homology of independent domains suggests that some aspects of the packaging mechanisms may be conserved across all bacteriophages; however, the reason for the observed differences in domain positions across the three proteins is unclear.

The portal (or connector) density is colored green, the structural RNA density is colored magenta, and the packaging ATPase density is colored purple. (C) Three large terminase structures from the T4 (PDB: 3CPE), Sf6 (PDB: 5IDH), and D6E (PDB: 5OE8) phages are depicted to highlight the unique domain arrangements found in each crystal structure. The ATPase domain is colored green, the lid subdomain is colored yellow, and the nuclease domain is colored blue. Reproduced from (A) Andrews, B.T., Catalano, C.E., 2013. Strong subunit coordination drives a powerful viral DNA packaging motor. *Proceedings of the National Academy of Sciences* 110 (15), 5909–5914. doi:10.1073/pnas.1222820110. (B) Morais, M.C., Koti, J.S., Bowman, V.D., *et al.*, 2008. Defining molecular and domain boundaries in the bacteriophage ϕ 29 DNA packaging motor. *Structure* 16 (8), 1267–1274.

The packaging ATPase complex assembles at a unique vertex of the viral procapsid, which houses the portal protein complex, a 12-mer ring structure that forms the pore through which DNA passes during translocation. It is known that the large packaging ATPases dock to the portal complex. However, it is not known which domain of terminase proteins binds to the portal. Cryo-EM data from the T4 and T7 bacteriophages suggest that the ATPase domain binds to the portal, while Fluorescence Resonance Energy Transfer (FRET) and some genetic and biochemical data suggest that the nuclease domain binds to the portal. This is an important issue to resolve, as the two orientations imply different mechanisms for certain aspects of motor function, such as DNA-gripping residues and force-generation mechanisms.

DNA Packaging Characteristics

Biophysical experiments, particularly single DNA molecule manipulation experiments with optical tweezers, have produced a wealth of quantitative data on the packaging process (Fig. 2). These experiments involve trapping and manipulating dielectric microspheres using focused laser beams. In one approach, used to study ϕ 29 and T4, an empty phage procapsid, with its motor complex attached, is tethered via antibodies to one of the microspheres while its genome is attached by one end via biotin-streptavidin labels to a second microsphere. Packaging is initiated when the laser brings these two spheres close enough for the packaging motor on one sphere to grab the free end of the DNA on the other sphere. In a second approach, used to study λ , a DNA-motor complex attached to one sphere docks onto an empty procapsid bound to a second sphere to initiate packaging. Subsequent packaging of DNA exerts a force on the DNA and the attached microspheres, and the magnitude of this force is determined by measuring the deflections (change in momentum) of the trapping laser beams. A commonly used measurement technique is the “force-clamp” in which a feedback control system is used to change the separation between the two trapped beads so as to apply a small constant stretching force to the DNA as it is being packaged, enabling the length of the DNA packaged to be tracked continuously as a function of time. These measurements have high sensitivity and can resolve force changes < 1 pN and displacements as small as ~ 1 bp in some experiments. Motor characteristics that have been determined include instantaneous and average packaging rates, motor pausing and slipping, and in some cases incremental translocation step sizes.

Packaging Speed

Viral DNA packaging is highly processive (Table 1). Single-molecule experiments showed that the ϕ 29 phage packages at a maximum rate (at $\sim 23^\circ\text{C}$) of ~ 200 base pairs per second (bp/s), the λ phage packages as fast as ~ 800 bp/s, and the T4 phage can package up to

Fig. 2 Single molecule experimental set-up and examples of data collected. (A) A schematic of the single molecule experimental set-up using optical tweezers to study the $\phi 29$ phage packaging process. In these early studies the bottom microsphere was held with a narrow glass pipette. In more recent studies both microspheres were trapped with optical tweezers. (B) DNA translocation distance vs. time data gathered on the $\phi 29$ system displaying dwell and burst phase behavior. During the dwell phase the motor does not package DNA while it waits for all subunits to be loaded with ATP. During the burst phase, four subunits hydrolyze ATP in quick succession to translocate 10 bp of DNA. (C) Nucleotide-dependent slipping of the T4 motor; the black lines are with a high concentration of non- (or slowly) hydrolyzable ATP analog, blue lines are with high ADP concentration, and red lines are with no nucleotides. Reproduced from (A) Smith, D.E., Tans, S.J., Smith, S.B., *et al.*, 2001. The bacteriophage $\phi 29$ portal motor can package DNA against a large internal force. *Nature*, 413 (6857), 748–752. doi:10.1038/35099581 with permission from Springer publishing. Nucleotide-dependent DNA gripping and an end-clamp mechanism regulate the bacteriophage T4 viral packaging motor. *Nature Communications*, 9 (1). doi:10.1038/s41467-018-07834-2 with permission from Springer publishing.

Table 1 Packaging speed and genome length

Bacteriophage	Maximum packaging speed (bp s ⁻¹)	Genome length (kbp)
$\phi 29$	200	19
λ	800	48.5
T4	2000	170

2000 bp/s. These rates appear to be roughly proportional to the length of the virus' genome: the $\phi 29$ phage genome is ~ 19 kilo base pairs (kbp), and the λ and T4 phage genomes are ~ 48.5 and ~ 170 kbp long, respectively. This proportionality ensures that each virus can package its genome within a relatively short window of time during the infection of the host cell.

The experiments also showed that the packaging speeds of the $\phi 29$, T4, and λ phages decrease with increasing applied load force. Similarly, packaging speed was found to decrease during packaging with the amount of DNA packaged in the capsid, suggesting that internal forces which oppose DNA confinement also slow down the motor. Recent studies of $\phi 29$ indicate that both internal load force and allosteric regulation of ATP binding regulate the motor speed in response to the amount and conformation of packaged DNA. Single-molecule studies of the λ phage revealed a sharp dip in packaging speed when $\sim 30\%$ of the genome was packaged. The interpretation of this feature is that it is due to capsid expansion which occurs in that system induced by a build-up of internal pressure due to the confined DNA, which temporarily reduces the load force acting on the motor.

The $\phi 29$ motor has been best characterized in terms of the kinetics of the mechano-chemical cycle, and because the motor translocates relatively slowly very high-resolution measurements of DNA translocation were possible. High stability optical tweezers measurements at high load forces revealed that $\phi 29$ translocates DNA in incremental steps of 2.5 bp per ATP hydrolyzed. These 2.5 bp steps are further grouped into 10 bp "bursts", during which four subunits package rapidly in sequence (Fig. 3). This sequence of rapid firing is termed the "burst phase". After the burst phase, the motor continues to grip DNA but does not package it. During this "dwell phase", the motor waits for ATP to bind to every subunit that had catalyzed ATP to package DNA during the burst phase. Interestingly, this implies that the multiple motor subunits are tightly coordinated and that one of the five subunits does not participate in DNA translocation and is understood to regulate the occurrence of bursts. It is currently unknown whether other phages also use a strictly coordinated dwell-burst packaging mechanism, as those phages package too quickly to resolve the dwell phase if it were to be present.

Fig. 3 Kinetic model for the dwell phase/burst phase cycle of the $\phi 29$ packaging process. ATP-bound subunits are labeled as T, ADP/Pi-bound subunits are labeled as D-P, and ADP-bound subunits are labeled as D. Electrostatic contacts with the DNA backbone are indicated in red. The “Special Subunit” grips DNA, but does not translocate. Reproduced from Chistol, G., Liu, S., Hetherington, C.L., *et al.*, 2012. High degree of coordination and division of labor among subunits in a homomeric ring ATPase. *Cell*, 151 (5), 1017–1028. doi:10.1016/j.cell.2012.10.031 with permission from Elsevier.

Force Generation

Viral DNA packaging motors are some of the strongest molecular motors identified in biology. Single-molecule studies on the $\phi 29$, λ , and T4 phages revealed that all three phages could overcome applied load forces in excess of 50–60 pN. For comparison, the skeletal muscle protein myosin can generate ~ 2 pN of force. In fact, the 50–60 pN measurements represent a lower bound on the generated force; at higher forces the procapsids were pulled off the microspheres and at ~ 65 pN the DNA helix sharply deforms. At high prohead filling levels internal forces contribute an estimated ~ 20 –30 pN and, combined with applied external forces ranging up to ~ 50 pN, suggest that these motors can produce forces of at least ~ 80 pN. ATP hydrolysis supplies ~ 18 kcal mol $^{-1}$ (~ 130 pN nm) of free energy. If a motor were to convert this energy into useful work with 100% efficiency, almost 155 pN of force would be available to translocate DNA by the 2.5 bp (~ 8.5 Angstrom) step size observed experimentally. Thus, the predicted packaging force magnitude of ~ 80 pN is within the realm of possibility, provided the motor achieves $\sim 50\%$ efficiency.

Pausing and Slipping

Although these motors are highly processive and capable of producing large forces, the packaging process is not without defects. Pausing and slipping (DNA leaving the procapsid) are induced at high external loads and if ATP concentration is lowered. Interestingly, pausing and slipping events are not proportionally induced in each packaging motor. For example, under high load force, the λ phage packaging motor pauses more but slips less than the $\phi 29$ motor. While packaging the fastest overall, the T4 phage has the most variable packaging speed.

Additionally, pausing and slipping is highly dependent upon the availability of nucleotides in the bulk environment. For instance, slippage is more frequent in solutions with low ATP concentration, while pausing is more frequent in conditions with small amounts of non-hydrolyzable ATP analog. Recent single-molecule experiments on the T4 phage in an ADP-rich environment showed that the motor appears to fluctuate between apo-like, ATP-like, and intermediate states.

DNA Packaging Mechanisms

The molecular mechanisms by which these enzymes package DNA are becoming better understood thanks to a combination of increased availability of high-resolution crystal structures, biochemical analysis of mutant enzymes, and computational modeling. These mechanisms include mechanochemical coupling, motor-substrate interactions, force generation, and motor coordination. However, these mechanisms are not mutually exclusive, and often perturbing one aspect has a cascade effect which perturbs other mechanisms.

Mechanochemical Coupling

Single molecule experiments in which $\phi 29$ translocation was studied with varying ATP concentration, varying applied force, and with mixtures of ATP and non-hydrolyzable ATP analog demonstrates that ATP binding does not induce the DNA translocation

step. Instead, it is likely coincident with product (inorganic phosphate) release. Because the nonhydrolyzable analog induces pausing and not slipping, ATP binding likely “cocks” the motor by causing the enzyme to grip DNA before translocation. Rapid solution exchange experiments with T4 also showed that the motor usually tightly grips the DNA when a non-hydrolyzable ATP analog is bound, while the DNA slips out rapidly when there is no nucleotide. Thus, it is evident that small changes within the ATP binding pocket must be sensed by the protein and then somehow converted into mechanical motion. The connection between the chemical steps of ATP hydrolysis and the mechanical motion of the motor is termed “mechanochemical coupling.” The mechanisms involved are generally expected to have features in common with related ATPases, such as AAA+ motors.

One such recently identified mechanism has been termed the “arginine toggle.” A unique structural element of packaging ATPase enzymes relative to other ASCE proteins is the strong conservation of an arginine residue at the 3 or 4 position of the canonical WA motif. Mutational studies of the λ , T4, P74-26, and D6E phage terminase proteins have provided evidence suggesting that the WA arginine is crucial for ATPase catalytic activity as well as mechanochemical coupling. Further computational studies of the T4, P74-26, and Sf6 terminase proteins predicted that the WA arginine toggles in and out of the binding pocket in response to ATP binding, and this toggling motion is part of the signal transduction pathway which informs the rest of the protein that ATP has bound. In this sense, it appears that the “arginine toggle” is conceptually analogous to the “sensor II motif” arginine found in related AAA+ motors.

A related family of ATPase proteins, helicases, were identified to use a “Q-motif” which also couples ATP binding to conformational change. This motif typically consists of a “YQ” amino acid pairing upstream of the WA motif responsible for binding the adenine ring of ATP. Sequence alignment suggested that the λ phage terminase enzyme contained a Q-motif, namely 46-YQ-47. Single molecule experiments of a Y46F variant displayed slower packaging rate and increased slipping, as well as higher sensitivity to applied force. This suggests that the Q-motif is responsible in part for mechanochemical coupling as well as force generation.

Motor-substrate Interactions

Many proteins that bind to DNA do so at specific sites dictated by short DNA sequence motifs. This allows for increased specificity and increased binding affinity. However, since these motors must package entire genomes, they must grip onto a wide variety of sequence motifs. Thus, sequence specific interactions are not employed by these motors, but instead they rely on non-specific interactions. Such interactions can be classified into two broad categories: electrostatic and steric. Although each base of DNA varies in hydrogen-bonding potential, each base is attached to an identical negatively-charged phosphate backbone. Thus, positively-charged residues located in the pore of the motor can non-specifically bind with these negatively-charged groups via electrostatic interactions. Further, the double-helix structure of DNA creates a major-groove and minor-groove which bulky protrusions could fit into, such that the motor grips DNA via steric interactions.

To test whether the motor primarily grips via electrostatic or steric interactions, single molecule experiments have been performed with structural modifications introduced to the substrate DNA. 10 bp sections of methylated DNA, which neutralizes the negative charge of the phosphate backbone, were able to be packaged with little change in kinetics compared to packaging regular DNA. However, DNA with 11 bp sections of methylated DNA often caused stalling or lengthy pauses in packaging. This suggests that the motor makes crucial electrostatic contacts every 10 bp of DNA. This behavior fits with known structural features as follows: the motor has pentameric stoichiometry and packages in 2.5 bp steps. One helix turn of DNA is 10.5 bp. Thus, every 10 bp of DNA approximately aligns the charged phosphate backbone with the same subunit.

Although the 11 bp insertions strongly affected packaging dynamics, the motor was able to accommodate insertions up to 30 bp long. This indicates that while electrostatic interactions are important, non-specific steric interactions are sufficient for DNA translocation. To test whether electrostatic interactions alone are sufficient for DNA translocation, DNA with 10 bp abasic phosphate backbone insertions were introduced to the system. This modification was also able to be packaged under low applied load, indicating that electrostatic interactions are sufficient at low forces. However, other modifications such as single-strand insertions, unhybridized bulges, and polymer insertions were also able to be packaged. Taken together, this evidence demonstrates that both non-specific steric interactions and attractive electrostatic interactions play roles in the translocation process.

There remains debate whether the ATPase domain or the nuclease domain of the terminase proteins interact with DNA during translocation. The ϕ 29 motor does not contain a functional nuclease domain, which suggests that the ATPase domain may primarily interact with the DNA. However, it is unclear if this is consistent across all packaging proteins. A model based on T4 cryo-electron microscopy data implicates the nuclease domain as gripping the DNA during translocation steps. However, biochemical data from mutant P74-26 terminase proteins identified that crucial DNA gripping residues reside in the ATPase domain and not the nuclease domain. Thus, it is unclear whether one model can explain protein-DNA interactions for all packaging motors.

Force Generation

Several models have been proposed to explain how these molecular machines generate the incredible forces necessary for complete genome packaging. Most models suggest that the force is generated by conformational changes within the ATPase packaging proteins that actuate a “lever” motion (Fig. 4), but one model suggests that the DNA segment threaded through the motor channel itself could be involved in force generation.

Fig. 4 Three proposed models for the motor force generation mechanism. (A) The scrunchworm model, indicating the motor gripping events needed to facilitate unidirectional motion of the substrate DNA. (B) A model proposed based on crystal structures of the P74-26 terminase enzymes in apo and ATP-bound states. The ATPase domain (N-terminal) grips DNA, and the nuclease domain (C-terminal) attaches to the portal. Rotation about the lid subdomain drives translocation. (C) The extended-to-compact transition model is depicted, proposed based on cryo-EM and X-ray data for the T4 motor. The nuclease domain (C-terminal) grips DNA and the ATPase domain (N-terminal) attaches to the portal. Alignment of charged residues across the domain interface drives the compaction process and DNA translocation. Structure and mechanism of the ATPase that powers viral genome packaging. *Proceedings of the National Academy of Sciences*, 112 (29), E3792–E3799. doi:10.1073/pnas.1506951112. (C) Migliori, A.D., Smith, D.E., Arya, G., 2015. Molecular interactions and residues involved in force generation in the T4 viral DNA packaging motor. *Journal of Molecular Biology*, 426 (24), 4002–4017. doi:10.1016/j.jmb.2014.09.023.

The “scrunchworm” model suggests that the translocation machinery primarily grips and releases DNA while the DNA is compressed and expanded. Coordination between gripping/releasing and compression/expansion could result in directional motion of the DNA. In this model, the force generated is a restorative force stored within the DNA itself and the motor is speculated to induce the DNA to go into the compressed conformation. Support for this model comes from molecular simulations demonstrating that DNA is expanded/compressed within the portal complex. Further, dsRNA and RNA-DNA heteroduplexes could not be packaged by the T4 motor, presumably because they cannot undergo the same compression/expansion as dsDNA.

On the other hand, more conventional models assume that the force to drive translocation is generated inside the motor proteins. One such model proposed for the T4 motor posits that the alignment and misalignment of charged residue pairs at the ATPase/nuclease domain interface drives translocation. Alignment of the charged residue pairs induces compaction, and misalignment induces expansion. If compaction occurred while the protein gripped DNA and expansion occurred while the protein did not grip DNA, this would result in unidirectional movement, and thus packaging. In this model, mechanochemical coupling of the ATP hydrolysis cycle coordinates the alignment and misalignment of the charged residue pairs. This model is supported by single molecule studies of motor protein mutants in which charged amino acids at the interface were substituted for residues of opposite charge. It was found that these residue changes lower translocation velocity and force generated by the motor.

Alternative models have been proposed for the P74-26 and Sf6 packaging motors based on solved crystal structures of the monomeric terminase subunits. In both cases the lid subdomain (a small motif within the ATPase domain) of the ATP-bound structure is rotated relative to the apo state. In these models, DNA is gripped by either the ATPase domain or a combination of the ATPase and nuclease domains. The rotation of the lid subdomain powers DNA translocation and passes DNA from one subunit to the next subunit, and mechanochemical coupling of the ATP hydrolysis cycle coordinates the lid subdomain rotation.

Motor Coordination

As mentioned above, the ϕ 29 motor has been shown to be highly coordinated overall, exhibiting a “dwell” phase during which no ATP is hydrolyzed, and a “burst” phase where four subunits consecutively hydrolyze ATP and translocate DNA. Coordination within the burst phase is beneficial for motor function. For instance, if two subunits attempted to translocate DNA simultaneously, they might spend two ATP hydrolysis events to translocate DNA 2.5 bp. If those two subunits instead were to translocate DNA consecutively, they would spend the same two ATP hydrolysis events to translocate DNA 5 bp. Thus, it is in the motor’s best interest to coordinate its subunits’ actions.

One identified mechanism for inter-subunit communication is a *trans*-acting “arginine finger.” The arginine finger protrudes from one subunit into a neighboring subunit’s ATP-binding pocket. This allows information about an ATP binding event in one subunit to be communicated to its neighbor, so that their actions can be coordinated. Biochemical studies have assigned the *trans*-acting arginine finger in several packaging motors, such those from the ϕ 29, P74-26, and D6E phages. Although sequence alignments suggest that the T4 packaging motor could also contain a *trans*-acting arginine finger, a pentameric model of the T4 packaging motor based on cryo-EM reconstruction places each subunit’s ATP-binding pocket distal from its neighbors, arguing against such a mechanism. Additionally, the Sf6 packaging motor does not appear to contain an arginine at the sequence alignment predicted site but it is possible that it utilizes a deviant lysine to accomplish the same goal.

Glossary

Capsid The protein shell of a virus. It consists of oligomeric structural subunits made of proteins called protomers.

Enthalpy A property of a thermodynamic system, is equal to the system's internal energy plus the product of its pressure and volume. In a system enclosed so as to prevent mass transfer, for processes at constant pressure, the heat absorbed or released equals the change in enthalpy.

Entropy Entropy is an extensive property of a thermodynamic system. It is closely related to the number of microscopic configurations that are consistent with the macroscopic quantities that characterize the system.

Metastability A stable state of a dynamical system other than the system's state of least energy.

Osmolyte Compounds that influence the properties of biological fluids. Their primary role is to maintain the integrity of cells by affecting the viscosity, freezing point, and ionic strength of the aqueous solution.

Osmotic pressure The minimum pressure which needs to be applied to a solution to prevent the inward flow of its pure solvent across a semipermeable membrane. It is also defined as the measure of the tendency of a solution to take in pure solvent by osmosis.

Persistence length A basic mechanical property quantifying the stiffness of a polymer.

Introduction

Different virus traits determine virus-host interaction with resulting dynamics and heterogeneity of viral populations. Investigating these traits is of fundamental importance for understanding viral replication pathways, viral diversity and fitness, as well as for improving the potency of treatments and viral vaccines. Structural virology has been instrumental in providing a detailed morphological description and classification of viruses and their receptors required for studies of traits influencing virus-host interaction dynamics. However, most of the structural studies have been focused on viral protein shell (termed the capsid) due to its symmetry, rather than on the encapsidated genome where the lack of symmetry prevents high-resolution analysis. Recent findings of pressure-driven viral DNA ejection into cells from phage, archaeal viruses and herpesviruses, have raised strong interest in understanding the role that packaged double-stranded (ds) DNA structure plays in dynamics of genome ejection and viral replication. Knowledge of the structure and directly coupled to its energetics of the encapsidated viral DNA reveals the mechanism of DNA packaging and release during viral replication. Furthermore, it provides insight into the dynamics of viral genome delivery into a host cell and subsequent replication dynamics.

A significant amount of work has been done to describe the structural arrangement and resulting energy of dsDNA packaged in bacteriophage capsids. As mentioned above, while the exact arrangement of dsDNA in the capsid has not been established, the current models combined with the experiments provide a reasonable estimate of the intracapsid DNA equilibrium energy. This energy, dominated by strong DNA-DNA repulsions and bending stress, results in pressure of tens of atmospheres that powers DNA ejection into a cell. We recently found that DNA packaged in phage λ and human herpes simplex virus type 1 undergoes a structural disordering transition from a solid-like to a fluid-like state. In a parallel study, it was shown that DNA packaged in a phage capsid does not have an equilibrium structure and is instead trapped in non-equilibrium conformational states since genome relaxation in the capsid occurs on a slower time scale than processivity of the packaging motor. These findings suggest that DNA packaged in a capsid is in a structural and energetic *metastable* state. Therefore, knowing the intra-capsid DNA equilibrium energy alone is insufficient for understanding of mechanism and dynamics of viral DNA ejection. This article describes the non-equilibrium changes in energy, structure and associated mechanics of encapsidated viral genome facilitating its ejection during viral replication. As will be reviewed here, the metastable state of the packaged viral DNA is an important trait affecting virulence and course of infection (where the term "infection" denotes the introduction of viral nucleic acid into a host cell by a virus). Phage and herpesvirus model systems are used interchangeably below due to major similarities in their DNA ejection and packaging mechanisms, as well as similar DNA packing densities resulting in essentially identical mechanical properties and structure of the encapsidated genome.

Equilibrium Energy and Structure of Intracapsid DNA

As mentioned above, many families of viruses, infecting all three domains of life, have stressed packaged genomes resulting in high internal capsid pressure. This pressure is generated by an ATP-driven packaging motor located at a unique capsid vertex, shown to be the strongest molecular motor known. Structural features of packaging motor components are shared by bacterial and archaeal dsDNA viruses and eukaryotic herpesviruses. The viral genome organization resulting from intra-capsid confinement is closely

Fig. 1 Cutaway views from cryo-EM reconstructions of (A) HSV-1 C-capsid and (B) phage λ capsid. HSV-1 and λ capsids are shown to scale. Owing to the icosahedral symmetry imposed during the reconstruction, concentrically packed DNA within the capsid becomes shells of density (green). The density maps are downloaded from the Macromolecular Structure Database of the European Bioinformatics Institute with accession codes EMD-1354 (HSV-1) and EMD-5012 (phage λ). Modified from Sae-Ueng, U., Liu, T., Catalano, C.E., *et al.*, 2014. Major capsid reinforcement by a minor protein in herpesviruses and phage lambda. *Nucleic Acids Research*, 42 (14), 9096–107. doi:10.1093/nar/gku634.

associated with its energetic state. The cryo-EM single particle reconstruction of DNA phage λ and human herpes simplex virus type 1 (HSV-1) shown in **Fig. 1** reveals that the entire capsid volume is filled with DNA extending all the way to the center of the capsid. Starting from the capsid walls there are well ordered, multiple concentric DNA layers. The layers are evenly spaced indicating that DNA has adapted an ordered repetitive structure characteristic for a liquid crystalline state. However, toward the center of the capsid the ordered layers disappear suggesting a less ordered DNA structure with lower packing density than in the periphery of the capsid. Similar dsDNA distributions within the capsids were also observed for other viruses. The DNA structure in viral capsids is mainly determined by DNA–DNA interactions, bending stress and packing defects. DNA–DNA interaction and DNA bending are two main energy terms determining the structure of the encapsidated DNA. At high packaging densities, DNA–DNA interactions are mediated mainly by electrostatic and hydration forces. Hydration forces arise from surface structuring of water on the macromolecular surface with a range of interactions of $\sim 15\text{--}20\text{ \AA}$, corresponding to 3–4 water layers on each DNA surface. It was shown that DNA confined in a phage capsid behaves very similar, in terms of interactions and structural ordering, to the multiple DNA arrays confined by a polymer in a bulk solution at equal inter-strand separations. However, the encapsidated DNA, unlike the condensed DNA arrays in the bulk, is strongly bent by the confining capsid walls. This is due to the fact that the dsDNA persistence length is of the same order of magnitude as the diameter of many viral capsids ($\sim 50\text{ nm}$). This leads to an extra bending energy term affecting the structure of the DNA in the capsid. (Persistence length defines the stiffness of a polymer, describing the minimum radius of curvature it can adopt by the available thermal energy. Bending it to a smaller radius requires additional work). To relieve the bending stress, helices are packed closer to the capsid wall, decreasing the bending radius (providing lowest curvature) and also decreasing the spacing, therefore increasing the interaction energy. At the same time the repulsive DNA–DNA interactions will push DNA strands as far from each other as possible, filling the entire capsid volume and maximizing the inter-strand separations. There is a trade-off between bending and interaction energies. Furthermore, when DNA is bending inside the capsid, the initial correlation between two helices that have slightly different radii of curvature is lost, and the mutual orientation between helices must be re-established. This leads to the packing defects that are absent for linear packaging of DNA in solution. Packing defects are required in order to re-establish a favorable phosphate-phosphate “phasing” of helices, reducing the repulsive interactions due to bending.

In order to experimentally dissect the thermodynamic determinants of DNA packaging and ejection energetics, isothermal titration calorimetry (ITC) was used to directly measure the heat released by DNA ejection from a bacteriophage. This approach allows one to address experimentally the relative weight and origin of enthalpic and entropic contributions to the free energy of DNA packing inside a phage capsid. The values of free energy, ΔG , obtained for packaged DNA were one order of magnitude smaller than the values of the enthalpy measured with ITC; the calculated free energy of ejection (ΔG_{ej}) was on the order of 10^{-17} J/virion while the measured enthalpy (ΔH_{ej}) was 10^{-16} J/virion for the wild-type DNA length (WT) phage λ at 25°C . This is due to the fact that the entropy associated with DNA packaging in the capsid is positive, reflecting an increase in the disorder of the system. This may appear surprising, mainly because when DNA is packaged it is becoming more ordered, leading to a reduction in conformational entropy. However, as the DNA helices come closer together in the capsid, the hydration properties of DNA change so that the ordered water molecules directly surrounding the DNA are released, increasing the net disorder of the system, thus increasing its entropy. This observation from ITC measurements suggests that the entropy of packaged DNA is strongly related to hydration.

The observations above describe the equilibrium properties of virally packaged DNA. However, it was found that intra-capsid DNA is not in its equilibrium state but has a metastable behavior. This metastability affects the mobility and related to it dynamics of DNA ejection from the capsid during viral infection. While DNA is always condensed inside the cell, it is not condensed to the same extent as inside a viral capsid. Other than in sperm nuclei, in vivo packaging densities range from $\sim 5\%\text{--}10\%$ by volume. DNA confined in viral capsids, on the other hand, is at the extreme end of the packaging scale where it is confined to $\sim 55\%$ by volume, forming a hexagonally ordered structure. At only a few angstroms of DNA–DNA surface separation (e.g., $7\text{ \AA}$ surface separation in WT DNA length of 48,502 bp packaged in phage λ), hexagonally ordered DNA has been shown to have very restricted mobility. It has been proposed that so-called Coulomb sliding friction between neighboring DNA helices plays a

Fig. 2 (A) Enthalpy of DNA ejection per virion (J) versus temperature for wt-DNA phage λ titrated into LamB solution. Dashed lines are drawn to guide the eye. ΔH_{ej} values were obtained as an average of six independent measurements for each sample. Vertical error bars are SEs. (B) DNA disordering transition, which occurs when the temperature is increased, originates close to the center of the capsid, where DNA is more stressed due to stronger bending and larger packing defects. (Left) Cross-sections of the top view of the capsid. (Right) A side view cross-section of the capsid, which illustrates that DNA closer to the center of the capsid is likely to be ejected first since, due to dsDNA bending stress constraints, it is the last DNA portion to be packaged in the capsid during phage assembly. The schematic illustration of DNA inside the capsid shows the ordering of an averaged DNA structure and not the arrangement of individual DNA strands. Modified from Evilevitch, A., 2018. The mobility of packaged phage genome controls ejection dynamics. *eLife* 7. doi:10.7554/eLife.37345.002.

significant role in mobility of DNA at high packing densities in the viral capsids. Indeed, it was found that interhelical sliding friction leads to a kinetically trapped, glassy DNA state inside the capsid. This high friction genome state was shown to significantly affect the rates of DNA packaging and ejection in vitro. This occurs from dragging closely packed negatively charged DNA helices past other helices. The external environmental factors (e.g., ionic conditions and temperature) along with DNA packing density in the capsid strongly affect the metastable state of intra-capsid DNA and facilitate the required mobility of the hexagonally ordered viral genome during the initiation of its ultra-fast ejection reaching 60,000 bp/s. Transition in the metastable states of encapsidated viral genome structure and its energetics associated with the ejection process are reviewed below.

Metastability of Intra-Capsid DNA Facilitating or Inhibiting Viral DNA Ejection

Virion metastability is one of the central concepts in virology. It implies that the virus, in order to successfully replicate, must be sufficiently *stable* to prevent spontaneous release of its genome outside the cell between infection events, and at the same time be *unstable* enough to release its genome during infection. Viral particles are therefore not inert structures and have not attained the minimum free energy conformation, separated by an energetic or kinetic barrier, prior to cell attachment and entry. Thus, viral structure plays an active role in genome delivery to the host cell. Viral metastability is mostly associated with structural transformations in the nucleocapsid and/or surrounding lipid envelope in response to changes in the virion's environment. However, this does not apply to motor-packaged dsDNA viruses (e.g., dsDNA phages and herpesviruses) whose capsid remains intact after the genome is released into a cell through a portal opening in the capsid structure. In these viruses, it is the encapsidated DNA rather than the capsid itself in these viruses that is metastable, where it can undergo a transition from a more ordered to a less ordered state. Atomic force microscopy (AFM) nano-indentation experiments have shown that these two states are characterized by a solid-like (ordered DNA) to a fluid-like (disordered DNA) mechanical transition of intra-capsid genome. This provides a mechanical shift affecting genome mobility. This mechano-structural transition is influenced by temperature, ionic conditions and/or DNA packing density in the capsid which either facilitate or inhibit genome ejection from a capsid into a host cell during viral replication. By mapping both energy (using ITC) and structure (using solution Small Angle X-ray Scattering, SAXS) of the packaged λ -genome a remarkable paradigm of physical adaptation of viruses to their physiologic environment of the host was found. It was shown that mobility of the packaged DNA in λ -capsid is "switched on" to a fluid-like state facilitating its release from the capsid at the most favorable ionic and temperature (37°C) conditions for *E. coli* infection. Correspondingly, the intra-capsid DNA is in a solid-like state inhibiting its released and infection under less favorable conditions for infection, preserving the infectious viral particle. Furthermore, the transition occurs only at the WT λ -DNA length (48,500 kbp) density packaged in the phage λ capsid, as opposed to the shorter DNA lengths of phage λ mutants.

The ITC provides the most direct method to measure the internal energy of the confined viral genome. Using ITC, the enthalpy change (ΔH) associated with DNA ejection from phage λ was measured as heat released when concentrated phage particles are titrated into a LamB receptor solution, which triggers DNA ejection in vitro. (LamB is an outer membrane maltoporin protein in Gram-negative bacteria which also serves as the phage λ receptor). Since the total volume of the system does not change during the DNA ejection in the ITC measurement, and the pressure is constant, the internal energy and the enthalpy (provided by ITC) are approximately equal. The enthalpy change associated with DNA ejection from phage is $\Delta H_{ej}(T) = \Delta H(T)_{DNA \text{ ejected}} - \Delta H(T)_{DNA \text{ inside phage}}$. $\Delta H_{ej}(T)$ can be determined versus temperature. Fig. 2(A) reveals a discontinuity in the approximately linear dependence of ΔH_{ej} on temperature for WT DNA length (48.5 kbp) ejection from phage λ occurring close to the physiologic temperature of infection and optimum ionic conditions for infection (10 mM MgCl₂ Tris-buffer). The discontinuity demonstrates an abrupt transition that is attributed to the DNA

inside the capsid. Prior to the transition, the absolute value of the ejection enthalpy change $|\Delta H_{ej}(T)|$ shows a strong linear increase with increasing temperature. This increase in the internal energy indicates an increase in the stress of the confined genome as temperature is being raised. At the transition temperature, T^* , the internal energy is reduced by almost half, suggesting partial relief of the stressed state. After the transition, $|\Delta H_{ej}(T)|$ shows only weak temperature dependence when the temperature is further increased to 42°C, see Fig. 2(A). This observation demonstrates that the DNA inside λ capsid can exist in two energy states. Thus, the critical genome stress is reached at temperature T^* and is required for the structural transition to occur. There is a strong dependence between the internal genome stress and the structural DNA transition in phage λ . The DNA stress in the capsid is regulated by both packaged DNA length and by the concentration and nature of the DNA counterions freely diffusing through the capsid wall of most viruses. E.g., lower DNA density in the capsid has larger spacings between packaged DNA helices, resulting in weaker repulsive interactions and lower genome stress. As a result, critical genome stress required for transition to occur is not achieved at lower DNA packing density in the capsid than intra-capsid density corresponding to WT λ -DNA length.

Solution small angle X-ray scattering (SAXS) is a powerful technique that provides structural information about the encapsidated genome. In parallel with the increasing inter-strand repulsions, the increase in temperature will decrease the DNA persistence length, leading to less bending stress. If the bending stress decreases and if there is room to expand in the capsid, then DNA-DNA interstrand spacings would increase and interaction energy decrease. However, with SAXS it was shown that the DNA-DNA spacing remains constant, suggesting that there is no room for DNA to expand in the λ -capsid. Instead, as a result of increasing repulsive interactions (due to packing defects) and decreasing bending stress with increasing temperature, the disordering DNA transition occurs, as confirmed by SAXS. This transition is suggested to take place closer to the center of the capsid, where DNA bending stress is stronger and packing defects are larger than for DNA closer to the capsid wall, making the DNA in the center more destabilized and therefore more sensitive to the increasing temperature. At the transition temperature, the DNA bending stress becomes sufficiently small, allowing a fraction of the ordered DNA layers closest to the capsid's center to undergo a disordering transition. The disordered DNA will have a lower packing density than the ordered DNA, which maximizes DNA-DNA spacings and simultaneously reduces the repulsive interactions and DNA-DNA sliding friction. This yields an overall lower energy state of the encapsidated genome and increases DNA mobility in the center of the capsid which is required for rapid DNA release during infection. DNA closer to the center of the capsid is likely to be ejected first since it is the last DNA portion to be packaged in the capsid during the phage assembly, due to the dsDNA bending stress constraints. The schematic representation of this transition behavior versus temperature is shown in Fig. 2(B).

While variation in the monovalent ion concentration has a small influence on intra-capsid DNA stress, polyvalent cations present in the bacterial cytoplasm, such as polyamines and Mg^{2+} , have been shown to have a strong effect on the repulsive interactions between packaged DNA helices. Since the free polyamine concentration in cells is very low as most polyamines are bound to cellular DNA and RNA, there is a particular interest in the effect of the Mg-ion concentration on the DNA transition temperature in phage λ at concentrations similar to those of free Mg^{2+} in vivo. Mg-ions are essential for both cellular metabolism, e.g., enzyme activity, protein synthesis, preservation of ribosome and nucleic acid structures, as well as the phage λ infectious cycle. It has been shown that a concentration of 10–20 mM of Mg^{2+} ions in the extracellular solution is critically important for optimum adsorption and infection of *E. coli* by phage λ . Mg-concentrations below or above 10–20 mM had a strong negative effect on the number of bacterial cells that could be infected. Interestingly, a similar Mg-concentration (~ 10 mM Mg^{2+}) has also been shown to provide optimum conditions for DNA packaging in phage λ and also corresponds to the free Mg-concentration in *E. coli* cytoplasm. Since the Mg-concentration affects DNA stress in the capsid (by freely diffusing through the capsid walls and screening the negative charges in the packaged DNA), it also strongly influences the transition temperature of the encapsidated genome. While T^* varies significantly with Mg^{2+} concentration, the most favorable Mg-concentration for phage λ infection of *E. coli* (~ 10 –20 mM) triggers DNA transition in the capsid precisely at the physiologic temperature of infection ($\sim 37^\circ\text{C}$). This striking correlation shows that the intra-capsid DNA transition mechanism in λ is evolutionarily adapted to both the ionic environment and temperature of its host (phage λ replicates in *E. coli* in the human gut at 37°C), suggesting its significance for viral replication. An analogous metastable DNA state inside the viral capsid is also present in HSV-1, where solid-to-fluid like DNA transition occurs close to 37°C . This suggests that the DNA transition mechanism regulating infectivity may be universal for many pressurized DNA viruses.

These observations suggest that dynamics of DNA ejection can be affected by a transition in mobility of the encapsidated genome, which can also influence viral replication dynamics and course of infection. This is discussed in the next section.

The Mobility of Packaged Genome Controls Ejection Dynamics

Gaining insight into the dynamics of viral gene delivery in a host cell during infection is critical for understanding the virus replication dynamics and viral fitness. We recently found a direct link between the structure (and its associated mobility) of the encapsidated dsDNA in phage λ and dynamics of initiation of its release from the capsid. Time-resolved ITC measurements provide ultra-sensitive detection of ejection dynamics from a phage population triggered by instant mixing with LamB λ -receptor in vitro, revealing the effect of mechano-structural DNA transition in a viral capsid on DNA ejection dynamics from a phage λ population. ITC is mainly used for thermodynamic analysis. However, it was recently demonstrated that it can be successfully used to measure reaction kinetics reflected by heat flow (so-called kinITC) due to the very short response time of modern ITC instruments.

It was shown that the solid-to-fluid-like intra-capsid DNA transition, is a determining factor for either rapid synchronized or slow desynchronized ejection dynamics from a phage λ population. At optimum temperature for infection (i.e., $\sim 37^\circ\text{C}$) and Mg-concentration ≤ 10 mM, the encapsidated DNA is in a fluid-like state and ejection events from the majority of the phage population are synchronized with DNA ejections occurring within ~ 10 s directly after phage adsorption to *E. coli* receptors (this time corresponds to DNA translocation time from a capsid). However, deviations from these conditions for infection (e.g., low temperature, high Mg-concentration) result in intra-capsid DNA being in a solid-like state where DNA is arrested in different conformations due to high interstrand sliding friction. This leads to a striking heterogeneity in phage ejection dynamics, displaying coexistence of populations with synchronized ejection events (where DNA is in a fluid-like state) and desynchronized stochastically occurring ejection events (where DNA is in a solid-like state). The latter presents one to two orders-of-magnitude slower ejection dynamics, ranging from minutes to tens of minutes, depending on salt conditions and temperature, compared to DNA translocation time from a capsid. This in vitro ejection dynamics behavior is in good agreement with earlier observations of temperature's effect on DNA injection dynamics from phage λ after preadsorption to *E. coli* culture. These findings also dismiss an earlier claim that stochasticity of DNA ejections from phage is solely controlled by capsid portal opening dynamics. These assumptions were based on earlier light scattering measurements of phage ejection dynamics that could not distinguish between synchronized and desynchronized ejection events.

The lytic-lysogenic decision is one of the most crucial factors determining virus population dynamics. Lytic course of infection is where a virus replicates immediately, leading to cell lysis and progeny phage release, while lysogenic infection is a latent state where phage DNA is integrated into a cell's chromosome without killing the cell. There are three early viral genes (CI, Cro and CII) which have been previously found to be involved in the decision-making process. CII appears to provide positive and negative feedback in the gene regulatory network. High levels of CII promote production of CI which leads to lysogeny, while low levels of CII promote production of Cro leading to bacterial cell lysis. It was recently proposed that the lysogeny-lytic cell decision initially occurs at the phage level through the timing of DNA delivery from multiple phages into a cell during infection. The timing of DNA injection from phage is what determines the onset of viral genome replication and gene expression because both phage DNA injection and DNA replication processes occur on comparable timescales. In turn, replication and expression dynamics of injected phage genomes determines how phages interact with one another when multiple phage particles are infecting a single cell. It was shown that lysogeny is more likely to occur when infecting phages interact cooperatively during cell infection. Synchronized injections result in immediate presence of DNA from multiple phages in a cell that can be integrated into cell's chromosome without competition for the progeny. Lysogeny results in the absence of selection, which allows various mutants to integrate and persist in the lysogenic state, leading to diversification of phage genes and adaptation to poor or new growth conditions. On the contrary, when DNA injections are desynchronized, few phage particles are delivering their genes faster than the rest of the phage population, resulting in competitive interactions. If the first phage to deliver its genome is lytic, it will override lysogeny, rapidly replicate itself using the cell's limited resources and therefore take a larger share of phage progeny. The asynchronous infection delays decrease the chance of lysogeny by also lowering CII viral transcription factor levels in the cell. It was shown that the cutoff time, where delayed phage infections of one cell no longer affect the lytic-lysogenic cell decision varies from few minutes to tens of minutes, depending on the multiplicity of infection, MOI (higher MOI results in shorter cutoff time), comparable to timescales for overall ejection delays observed in ITC measurements. This suggests that ejection delays resulting from solid-like DNA state in the capsid will increase cell lysis probability.

These in vitro findings suggest a new paradigm affecting virus population dynamics – mechano-signaling mediated by packaged DNA structure in phage λ . The environmental factors regulating the mechanical transition between solid- and fluid-like intra-capsid DNA states strongly influence the timing of genome ejections. In vivo, desynchronized ejections from a phage population lead to competition between phage genomes, affecting the rate of phage gene replication and transcription as well as the lysogeny-lytic cell decision. Given similarities between phage λ and herpesviruses in their mechanism of pressure-driven DNA ejection (where a temperature-induced solid-to-fluid like DNA transition was observed in both viral systems), the new insights into the lysogeny-lytic decision process for phage provide intriguing prospects for understanding of latency mechanism in herpesviruses. Indeed, analogies between phage and herpesviruses in other regulatory factors that affect viral latency have been previously observed.

Many viruses have been shown to have pressurized genomes inside their capsid. However, in order to place this important observation in the biological context of viral infection, it is critical to demonstrate the role that capsid pressure plays in viral genome delivery into a cell. Next Section describes the definitive demonstration of a pressure-dependent infection mechanism in viruses by showing that pressure-driven DNA ejection from HSV-1 capsids into a host cell nucleus is inhibited when intra-capsid DNA pressure is “turned off”.

Pressure-Driven Release of Viral Genome Into a Host Cell is a Mechanism Leading to Infection

All eukaryotic DNA viruses, with the exception of poxviruses, deliver and replicate their genomes within the nucleus. In addition, retro-viruses transport their genomes across nuclear membranes in order to replicate after they have reversely transcribed their single-stranded (ss) RNA to dsDNA. The mechanism of this most significant step of infection, viral DNA entry into the host nucleus, remains poorly understood for the majority of viruses. Despite previous measurements of intra-capsid DNA pressure in phage and herpesvirus, the role that capsid pressure plays for intra-cellular viral genome delivery has not been previously

Fig. 3 After binding at the outer membrane (Fig. 3(a)), viruses enter the cell cytoplasm and are transported toward the nucleus (Fig. 3(b)). The viral capsid ejects its genome upon docking to a nuclear pore complex (Fig. 3(c)). From Bauer, D.W., Huffman, J.B., Homa, F.L., Evilevitch, A., 2013. Herpes virus genome, the pressure is on. *Journal of the American Chemical Society* 135 (30), 11216–11221. doi:10.1021/ja404008r.

demonstrated. The reconstituted capsid-nuclei experiments below provide a demonstration of a nuclear entry mechanism of DNA from HSV-1, driven by high mechanical pressure of the encapsidated viral genome.

Herpesviruses consist of a dsDNA genome packaged within an icosahedral capsid that is surrounded by an unstructured protein layer, the tegument, and a lipid envelope. Fig. 3 illustrates the HSV-1 infection process as observed by ultrathin-sectioning transmission electron microscopy (TEM). After binding at the outer membrane (Fig. 3(a)), viruses enter the cell cytoplasm and are transported toward the nucleus (Fig. 3(b)). The viral capsid ejects its genome upon docking to a nuclear pore complex (NPC), which forms a passageway for molecular traffic into the nucleus (Fig. 3(c)).

To investigate the effect of capsid pressure on the single step of viral DNA ejection into a nucleus, cell nuclei were isolated and reconstituted with cytosol supplemented with an ATP-regeneration system. This reconstituted-nuclei assay avoids interference from other processes occurring within the cell during viral replication. The reconstituted nuclei system also accurately reproduces capsids-nuclei binding and nuclear transport of the herpes genome into living cells and it was previously shown that purified HSV-1 capsids bind to NPCs on isolated nuclei and eject their DNA into nuclei. To provide the evidence that intra-capsid DNA pressure is responsible for DNA release from a herpesvirus capsid into a cell nucleus, it was demonstrated that when the capsid pressure is “turned off” with addition of an external osmolyte, herpes capsids bound to NPCs do not eject DNA into a nucleus, while the ejection is completed successfully without osmolyte addition. The external osmotic pressure in solution surrounding the capsids effectively eliminates genome pressure in the capsid when it matches the pressure of the packaged DNA. As shown in Fig. 4, the viral genome ejection from HSV-1 through the NPCs into a cell nucleus can be completely suppressed in the presence of the biologically inert osmolyte polyethylene glycol (PEG) 8 kDa at 30% w/w corresponding to 20 atm of osmotic pressure matching that of DNA pressure in the capsid. While the term “infection” usually refers to both viral genome transport into the cell and subsequent replication of the virus, the primary infection by several types of herpesviruses (including HSV-1) is latent (i.e., the herpes genome is translocated into the host nucleus, without subsequent genome replication). Thus, the osmotic suppression assay, combined with the reconstituted nucleus system, provides a demonstration of a pressure-dependent mechanism of herpesvirus infection focused on the viral genome translocation step.

Concluding Remarks

Correlating structure and energetics of the encapsidated genome with the efficiency of viral replication provides a unique approach to explore the connection between *physical* and *genetic* aspects of viral evolution, and creates novel opportunities for control of viral infections. Various aspects of *genetic evolution* have been investigated in the field of virology. The *physical aspects* of viral evolution, however, are less understood. Recently, an intimate relationship was found between the physical and genetic evolution of dsDNA viruses. Specifically, it was shown that the physical limit of DNA length imposed by the capsid volume has led to gene overlap evolving as a mechanism for producing more proteins from the same genome length. This demonstrates how a *genetic mechanism* has evolved from a *physical* constraint by the capsid on the packaged genome density. Similarly with this finding, the data reviewed in this article suggest that the genome packing density in a viral capsid is unique and highly conserved. This precise packing density not only determines the number of genes required for replication, but also creates an internal stress in the capsid required for the solid-to-fluid like DNA transition to occur at the temperature of infection. Such intracapsid DNA transition facilitates initiation of DNA delivery from viral capsid into a cell. E.g., there is evidence that the packaged genome density in phage λ corresponding to WT λ -DNA length (as opposed to the shorter λ -DNA length mutants), presents the most energetically and structurally optimized balance between genome mobility and its internal stress, both of which are required for efficient DNA ejection from the capsid. DNA transition occurs once the critical DNA stress level in the capsid is reached, which are in turn controlled by the temperature and the ionic conditions of the surrounding solution. The DNA transition in the capsid occurs precisely at the physiologic

Fig. 4 Ultrathin-sectioning EM visualization of the osmotic suppression of DNA ejection from HSV-1 capsids into reconstituted cell nuclei [Isolated cell nuclei with added cytosol with ATP regeneration system. Cytosol contains importin- β required for efficient HSV-1 capsid binding to NPCs.] Negative control at 4°C without added PEG and without ATP-regenerating system, shows that no ejection from nuclei bound C-capsids occurs. Positive control at 37°C shows complete DNA ejection from C-capsids bound to isolated cell nuclei supplemented with cytosol ATP-regenerating system. EM shows that the addition of 30% PEG 8 kDa (corresponding to 20 atm of osmotic pressure) to reconstituted capsid-nuclei system, inhibits DNA ejection from HSV-1C-capsids into host nuclei through the NPC. Thin arrows show DNA-filled capsids, and bold arrows show empty capsids that ejected DNA. 1. Bar 500 nm. 2. Bar 90 nm. Modified from Brandariz-Nunez, A., Liu, T., Du, T., Evilevitch, A., 2019. Pressure-driven release of viral genome into a host nucleus is a mechanism leading to herpes infection. *eLife* 8. doi:[10.7554/eLife.47212.001](https://doi.org/10.7554/eLife.47212.001).

temperature of infection (37°C) and at the most favorable external Mg^{2+} -concentration for phage λ adsorption to *E. coli* and subsequent replication. This suggests an evolutionary adaptation of the intracapsid DNA transition mechanism to the temperature and ionic environment of its host.

The remarkable observation of mechano-regulation of phage genome ejection dynamics can be compared to gene expression regulation in meters-long, tightly packaged chromosomal DNA in eukaryotic cells, where gene expression is controlled not only by genetic regulation but also by mechanical properties of DNA in nucleosomes. Environmental stress factors, such as an abrupt change in temperature or in ionic conditions, were demonstrated to play a major role in the mechano-regulated gene activation process, turning certain genes on and off, in a process termed epigenetics. Similarly, temperature and ionic conditions control the mechanical properties of virally encapsidated DNA and act as an on-off switch between synchronized and desynchronized ejection dynamics. This can influence timing of viral replication and the lytic-lysogenic cell decision process.

Analogously to DNA pressurized phage capsids, high intra-capsid DNA packing density resulting in tens of atmospheres of pressure is a distinctive trait of all nine human herpesviruses. This strongly suggests that pressure-driven entry of viral DNA into the host nucleus during infection is universal to all herpesviruses. Other types of viruses also involve replication steps dependent on the pressurized state of the intra-capsid genome. For instance, during genome packaging, reoviruses replicate ssRNA to dsRNA inside the capsid, which results in genome packaging densities similar to that of herpesviruses. Such intra-capsid replication could be impacted, at least in part, by generation of internal pressure resulting from the increasing genome packaging density as newly synthesized dsRNA continues to fill the internal capsid volume. Another example is HIV, where similar to herpesviruses, HIV capsids dock to NPCs at the nucleus and release transcribed dsDNA through the NPC channel. It was recently shown that the reverse transcription process from ssRNA to dsDNA inside the HIV capsid is associated with increasing internal DNA pressure. The experiments summarized in this article provide the necessary tools for exploration of pressure-regulated replication in these viruses.

Glossary

Assay An experiment used to assess or measure a property of interest.

Genome The entirety of genetic material present in a cell or organism.

LPS Lipopolysaccharide; a molecule comprised of fatty acid and repeating sugar units that decorates the outer membrane of Gram-negative bacteria and varies widely between species and genera.

Omp Outer membrane protein; a protein found in the outermost membrane of Gram-negative bacteria.

Tail Phage structure comprised of several proteins through which many bacteriophages identify and bind to their host; the tail is bound to the phage capsid, which carries genomic information.

Transposon A sequence of DNA that can insert itself into or change its location in the genome.

History and Overview

Shortly after the discovery of bacteriophages, scientists became interested in multiple aspects of their infection cycle. However, the initial stages of infection – host recognition and attachment – received relatively little attention until three decades later in 1951, when Garen and Puck described two distinct steps during bacteriophage T2 attachment to its host *Escherichia coli*. This two-step process has since been described for many well-characterized bacteriophages. The first step is reversible, meaning the phage can unbind and has not committed to infection. The second step is irreversible and the particle commits to infecting the host. Subsequent experiments determined that the second step involves proteins in the bacterial membrane, but the identity of these proteins was not determined until the 1970s.

Since those initial studies, our knowledge of phage receptors has grown exponentially. We now know that for many Gram-negative bacteria and their associated phages, the primary receptor is typically the lipopolysaccharide (LPS), capsular layer, flagellum, or pilus. At this stage, if the phage has attached to an incompatible host cell, it is still able to detach and search again for a suitable host. If the host is compatible, the phage reaches its secondary receptor by either degrading the LPS or the capsular layer, or by moving closer to the cell *via* rotary action of the host flagellum or retraction of the pilus. If the secondary receptor is compatible, the particle binds irreversibly to this host protein and its genetic material is ejected into the host (**Fig. 1**). Developing better techniques, as discussed later in this article, has been critical to our understanding of membrane proteins and how bacteriophages interact with them.

While bacteriophages as a whole employ vastly different strategies for primary receptor recognition, secondary receptors tend to fall into a few main classes of membrane proteins. This article will focus on secondary receptors by covering a few common techniques and methods to study membrane proteins, the characteristics of outer membrane proteins (Omps), and some of the known interactions between phages and host Omps. Within this context, the ecology and evolution of these interactions will be discussed, along with the importance of studying these interactions for use in phage applications.

Fig. 1 Representation of tailed bacteriophages interacting with the outer membrane of a Gram-negative bacterium. Membrane proteins are colored using the scheme in **Fig. 2**. Representative myovirus (purple), siphovirus (orange), and podoviruses (blue) are shown interacting with LPS and/or Omps *via* their tail proteins.

Techniques and Methods for Studying Phage Receptors

Since the initial studies from the 1950s, scientists have developed dozens of methods for identifying and studying the membrane proteins that bacteriophages use as secondary receptors. Some of these have been used for decades, including forward genetic screens and gel electrophoresis. Others are still being developed, such as single-gene deletion libraries and methods using advanced microscopy. [Table 1](#) presents a summary of these methods along with strengths and weaknesses. A more in-depth discussion of each is presented at the end of this article.

Once the receptor is identified from genetic or protein screens, and once its structure and/or function has been determined by atomic or low-resolution techniques, scientists can begin to visualize how the phage interacts with its receptor in the context of the native host. This question can be investigated by *in vivo* approaches such as time-lapse fluorescence microscopy and cryo-electron tomography (cryo-ET). These techniques visualize an entire population of phages interacting with their hosts or intact membranes.

Time-lapse fluorescence microscopy uses fluorescent markers, which can selectively dye either the host or the phage. A series of images taken during the course of the infection are then stitched together to form a movie of the infection process. This method can show the timing of host binding and genome ejection, as well as the distribution of entry sites on hosts.

Another direct visualization technique is cryo-ET. Similar to cryo-electron microscopy (cryo-EM), this involves flash-freezing populations of cells being infected with phage in vitreous ice and imaged in the transmission electron microscope. Host mutants called “mini cells” or outer membrane vesicles are useful to replace bona fide cells, as these limit the thickness of the specimen. The sample is then tilted to capture images from many different angles, and image reconstruction techniques are employed to create a more complete 3D picture. With cryo-ET, the image reconstruction results in being able to visualize the whole volume of the sample. From cryo-ET experiments, researchers can see details about the global structure of the phage tails and channels into the host membrane. Since flash freezing stops biological processes within milliseconds, this technique can capture phages at various stages of infection, letting scientists see the sequence of events more clearly.

Properties of Receptor Proteins

Through both classical and modern techniques, scientists have identified many common properties of phage receptor proteins of Gram-negative bacteria. Numerous well-studied phages infect intestinal – or enteric – bacteria. These include species of *Escherichia*, *Klebsiella*, *Salmonella*, *Shigella*, and *Yersinia*. The Omps used by many phages infecting these species are listed in [Table 2](#).

The vast majority of proteins found in the outer membrane are β -barrels, which are proteins rich in β -sheets that twist to form a barrel shape. These barrels are then embedded in the membrane, oriented as channels through which molecules can move into or out of a cell. Many of these proteins have α -helical or disordered loops connecting the β -sheets. Additionally, the majority have larger extracellular domains than periplasmic, or between-membrane, domains. Some of these proteins are involved in the transport of small molecules or nutrients, while others are able to sense membrane stress or contribute to membrane biogenesis. Many have unknown functions. Regardless of their role in bacteria, these proteins can be co-opted by bacteriophages to identify and gain access to their host. Representative structures from this list are shown in [Fig. 2](#).

Bacteriophages use their aptly-named receptor binding proteins to bind their specific host receptor. These receptor binding proteins, which are located on the surface of the phage particle, can recognize a suitable host and trigger a conformational change, resulting in the phage genome moving across the membrane. Many bacteriophages have specialized protein machinery called tails to accomplish this, with receptor binding proteins located on tail fibers or tail spikes. Non-tailed phages can identify their host *via* spikes directly attached to the capsid. Tailed phages, which are classified according to morphology, use different mechanisms of host binding and genome ejection depending on the tail. The three most common families of bacteriophage are the *Myoviridae* (long, contractile tails), *Siphoviridae* (long, non-contractile tails), and *Podoviridae* (short tails).

Several phage-host pairs have been studied in detail to determine the interactions between the host receptor and the phage's receptor-binding proteins. Some of these include the siphovirus lambda (λ) and its receptor LamB; siphovirus T5 and its receptor FhuA; and the podovirus Sf6 and its receptors OmpA and OmpC. These model systems have given us a wealth of information about genetics, protein-protein interactions, and predator-prey dynamics.

Bacteriophage λ and its receptor LamB is a classic system for studying phage-host interactions. The LamB outer membrane protein forms a homotrimer consisting of three β -barrels and functions as a maltose and maltodextrin transporter. The initial model of λ and LamB binding was based on the isolation and characterization of λ -resistant bacteria by Thirion and Hofnung in 1972. These researchers observed that the bacteria were also unable to use maltose as a carbon source, but the exact mechanism for this was unknown. The following year, Randall-Hazelbauer and Schwartz fractionated bacteria, separating the membranes and other components of the bacterial cell *via* ultracentrifugation. The end result is “fractions” of the sample that each contain a specific biomolecule: only membranes, only DNA, only ribosomes, *etc.* By doing this, they learned where this “ λ -resistance factor” was located in the cell: the outer membrane.

Once the specific protein was known, researchers could focus on a more in-depth characterization. Initially, they used directed genetic screens to determine which mutations affected either antibody binding or protease digestion of LamB. This information told researchers which regions of the protein were likely exposed to the extracellular environment and available for antibody binding or protease digestion. Mutations in LamB that made the bacteria resistant to λ could then be compared to these putative

Table 1 Techniques for studying bacteriophage receptor proteins

	<i>Pros</i>	<i>Cons</i>
Techniques for receptor identification:		
Genetics		
Resistance mutants	● Fast (<1 day) ● Simple and inexpensive ● Can process large populations (> 10⁸ cells) in a single experiment	● Mutants can arise from many steps in life cycle, not just receptors ● Resistant host may have multiple mutations complicating interpretation ● Binary results only: resistant or susceptible ● Redundant results if multiple genes contribute to a pathway
Single gene deletion library	● Systematic: checks all non-essential genes ● “Clean”: isogenic populations and a single, sequenced mutation per host	● Genetic tools are not available for all hosts ● Expensive and time consuming to generate
Transposon libraries	● Libraries can be generated from a single starting population ● Non-binary: can also identify genes that delay and accelerate infection	● Multiple genes contributing to the same pathway can make interpretation difficult
Protein-based		
Binding assays	● Detects direct binding	● Non-specific host components can co-purify
2D Gels	● Narrows down a few possible candidates instead of screening an entire library	● Receptor/phage interactions may be too transient to effectively capture
Chemical crosslinking		● The receptor might be present but not detected
Mass spectrometry		
Techniques for receptor characterization:		
Atomic/near atomic resolution		
Crystallography	● Provides detailed information about the receptor, including the position of all important atoms (amino acids or chemical bonds)	● Requires purification: not possible or practical for all cell components
Nuclear Magnetic Resonance (NMR)	● Shows regions that are flexible	● Not all substances readily crystallize.
Cryo-electron microscopy (cryo-EM)		● Size may be a limiting factor: either too large for NMR or too small for cryo-EM.
Lower resolution		
Oligomeric state: Gel shift, analytical ultracentrifugation, native mass spectrometry	● Provides basic information about the overall degree of folding at the level of tertiary or secondary structure	● Resolution is too low for specific details
Optical: Circular dichroism, fluorescence	● Can be used to determine the number of copies of a protein within a complex ● Can be used to assay how dynamic or stable a receptor is	● Membrane proteins often are purified in detergents, which may interfere with some of these methods ● Requires protein purification and extensive optimization
Techniques for characterization of phage-host interactions:		
Interaction location		
Site directed mutagenesis experimental evolution	● Identifies specific amino acids or regions of a protein that contribute to binding	● Some structural information is needed to guide the experiments ● Individual changes may result in subtle phenotypes ● Requires genetic tools such as engineering or sequencing approaches
Chemical crosslinking	● Identifies specific amino acids or regions of a protein that contribute to binding	● Directed approaches may be limited if the structure of the receptor is not known ● Non-specific crosslinking often occurs
Interaction dynamics		
Time-lapse fluorescence microscopy	● Native conditions	● Expensive and time consuming
Cryo-electron tomography (cryo-ET)	● Can directly visualize many distinct infection events	● Whole cells are often too thick for cryo-ET, so mini cells or outer membrane vesicles are needed (less-native)

(Continued)

Table 1 Continued

	<i>Pros</i>	<i>Cons</i>
Computation	● Looks at very complex landscapes including lipids, proteins, LPS, <i>etc.</i> ● Accesses conditions not easily achieved in laboratory settings ● Easily repeatable	● Currently limited to small time scales ● Some structural information is needed to guide the experiments
<i>In vitro</i> kinetics	● Can be used to determine strength of binding interactions ● Rates of binding can be determined ● If the receptor has enzymatic activity this can be studied as well	● Requires protein purification; not all receptors remain active when purified

extracellular sites to see where the phage might be binding. Most of these resistant bacteria contained mutations that mapped to the disordered protein strands (loops) 4, 5, 6, and 8 of LamB. Although a majority of these mutations affected simple binding of λ to host, a single amino acid immediately adjacent to loop 8 was also identified as critical for infection. This mutation, which resulted in glycine 401 being changed to aspartate, allowed the phage to bind but prevented genome ejection.

To examine how λ receptor binding proteins worked, researchers used a combination of methods similar to those described for LamB – examining antibody binding sites and genetic studies – as well as some early techniques in electron microscopy. They determined that λ binds to its host *via* protein J, which forms the needle-like tip of the tail. Images from the electron microscope showed gold-labeled J proteins interacting directly with the cell membrane of wild-type bacteria, but not with a mutant cell lacking *lamB*.

Although λ was one of the earliest phages to be studied in detail, it is still highly relevant in modern techniques. This includes dynamics experiments regarding λ “searching” for receptors using single-cell fluorescence microscopy and utilizing the extensive genetic screens made possible by the KEIO collection – a library of single gene deletion mutants including all non-essential genes in *E. coli* – to determine which genes are important for infection. Besides receptor interactions, this bacteriophage is also used extensively to investigate ecological and evolutionary questions.

After λ , one of the next rising stars in phage-host interactions was bacteriophage T5 and its receptor FhuA. From the late 1970s through the 1980s, several groups determined that the tail fiber, denoted pb1, binds to the O-antigen of LPS during the first step of attachment. They also characterized two other proteins involved in host attachment and entry: pb5, which we now know binds specifically to FhuA; and pb2, which is involved in translocating the DNA into the host cell. The pb5 and FhuA binding interaction was first proposed by Heller and Bryniok in 1984. These researchers isolated a T5 mutant that infected wild-type cells more slowly than wild-type T5 and were completely unable to infect cells lacking the O-antigen: a specific arrangement of sugars on LPS that are often recognized by phages. Instead of a mutation in pb1, which they knew bound to the O-antigen, they mapped the mutation to a separate protein, pb5. They hypothesized that this mutant depended on pb1 sticking to O-antigen for a longer amount of time. This would increase the probability that the phage could bump into and bind to its protein receptor. Since the mutant pb5 could not bind as efficiently to the protein receptor, the phage relied on O-antigen to stick long enough to find its receptor. The researchers then treated cells with ferrichrome, which binds selectively to and inhibits FhuA transport of iron, and saw that this treatment caused the mutant phage to bind even less. From these experiments, they determined that FhuA, which the bacteria uses for iron transport, was also the protein receptor for phage T5.

The role of pb5 as a receptor-binding protein was later confirmed by additional biochemical and structural experiments. Initially, this was investigated much like the phage λ and LamB interaction, using inhibitory peptides to determine which regions of the receptor were recognized by the phage. In 1995, Killmann *et al.* investigated the binding regions of FhuA-dependent phages T1, T5, and ϕ 80. They determined that all three phages use the same large extracellular loop of FhuA, with some minor variation in the exact regions of binding. In 2001, Böhm *et al.* used cryo-EM to look at T5 bound to FhuA-containing vesicles. The following year, Plancon *et al.* purified pb5 and FhuA to look at their binding interaction *in vitro*. They performed a battery of assays to measure DNA ejection rates, the stoichiometry of binding, and the stability of the complex in different denaturants and at a range of temperatures. The combination of these studies has given us a much better picture of where, when, and how T5 recognizes this protein.

A number of bacteriophages can use more than one secondary receptor to infect its host, though these are less well-studied than bacteriophage that rely on a single receptor because of the complicated nature of screening for phages that use more than one protein. In contrast to the systematic genetic approaches taken to identify receptors for λ and T5, the identification of the host receptors used by bacteriophage Sf6 was more serendipitous. When purified phage particles were analyzed by separating the proteins in a gel matrix, two mystery proteins appeared on the gel along with the expected structural proteins. These proteins were later identified by mass spectrometry as OmpA and OmpC by Parent *et al.* (2012). Since these proteins were caught in the act of associating with bacteriophage particles, the researchers tested this further *via in vitro* genome ejection assays and mutational analyzes. To confirm that OmpA was a true secondary receptor, all the components for genome ejection – LPS, OmpA, and phage – were purified individually,

Table 2 Common bacteriophage receptors in Gram-negative bacteria

Outer membrane protein	Species	Bacteriophage(s)	
OmpA	<i>Escherichia coli</i>	TuII	K3
		K4	K5
		Ox2	Ox3
		Ox4	Ox5
		M1	Ac3
OmpC	<i>Shigella flexneri</i>	Sf6	
	<i>Escherichia coli</i>	T4	Tulb
		Me1	PA2
		Hy2	SS4
		434	SS1
		PP01	TP2
	<i>Salmonella enterica</i>	Gifsy-1	Gifsy-2
OmpF	<i>Shigella flexneri</i>	Sf6	
	<i>Klebsiella pneumoniae</i>	GH-K3	
	<i>Escherichia coli</i>	T2	Tula
		TP1	K20
		TP2

Note: Modified from Hubbs, N.B., 2017. Hijacking the Cell: How Bacteriophage Sf6 uses *Shigella flexneri* Outer Membrane Proteins for Infection. Michigan State University. doi:10.25335/M5J19S.

Fig. 2 Structures of representative outer membrane proteins, with extracellular domains shown in blue, transmembrane domains in red, and periplasmic regions in gray. Structures were obtained from the Protein Data Bank (PDB) with accession numbers as follows: OmpA (1BXW), Ail (3QRA), OmpX (1QJ9), OmpT (1I78), Tsx (1TLY), FadL (1T16), BtuB (1NQE), FepA (1FEP), FhuA (1QFG), OmpF (3POX), OmpC (3UPG), LamB (1AF6), PhoE (1PHO).

mixed in a test tube, and incubated. No genome ejection was observed in tubes with only phage, with phage and LPS, or with phage and OmpA alone; however, when a tube containing all three components was incubated, the phage genome was ejected. This indicates that both LPS and OmpA are necessary and sufficient for the phage to infect its host.

In vivo, Sf6 plating efficiency was tested on wild type cells, cells lacking either OmpA or OmpC, or cells lacking both OmpA and OmpC. Parent *et al.* determined that cell survival was much higher for the double *ompA/ompC* mutant compared to either the single mutant or the wild-type bacteria. This suggested that Sf6 can use either of two receptors to infect its host. In addition to plating experiments, cryo-EM studies showed that Sf6 can still bind to outer membrane vesicles produced from cells lacking either OmpA or OmpC but not from cells lacking both. Using plaque assays, they then screened for mutagenized *ompA* clones that would not restore plaque formation and determined that for Sf6 to recognize and bind to OmpA, the critical regions were extracellular loops extending from the β -barrel. With a 10-fold reduced plating efficiency, Sf6 is probably able to use more than two secondary receptors, as cells lacking both these receptors are not fully immune to Sf6. The identity of this mystery third receptor, or if there are even more than three, is currently unknown.

Another system that has been characterized is the *E. coli* phage T2 and its two receptors, OmpF and FadL. Only bacteria lacking both membrane proteins OmpF and FadL are immune to T2. OmpF was the first protein receptor identified for T2, but the ability of T2 to still infect OmpF-negative cells led to the discovery of FadL by Morona and Henning in 1986. To do this, Morona and Henning generated a transposon library in a strain lacking OmpF, then screened the strains of their library to see which mutants could survive T2 infection. Subsequent mapping of these T2-resistant strains indicated that the *ttr* locus was important for T2 infection. This locus encodes FadL, an outer membrane protein involved in fatty acid transport. Given the genetic data and location of the protein in the outer membrane, this was determined to be the other secondary receptor of T2. These researchers also determined the relative preference of T2 for its receptors. Outer membranes isolated from cells lacking OmpF were much more

effective in neutralizing T2 when compared to outer membranes isolated from cells lacking FadL, suggesting a much stronger interaction between T2 and FadL.

While many phages may not initially use more than one receptor, they can adapt to use a different or additional secondary receptor when propagated on mutant bacterial strains that lack the phage's preferred receptor. These mutants, known as host range mutants, can use a different outer membrane protein for infection and may or may not lose the ability to use the original. These types of studies have mostly been done for the bacteriophages Tula, M1, Ox2, all of which infect *E. coli*. Bacteriophage Ox2 uses the outer membrane protein OmpA for infection and has been shown to develop mutations in its genome to use OmpC or OmpX. When propagated on a strain lacking OmpA or a modified version of OmpA, Ox2 mutants that could use OmpC for infection were isolated. One mutant, Ox2h5, could not infect a strain lacking OmpA, while the two other mutants Ox2h10 and Ox2h12 could still infect this strain. These two mutants were further propagated on a strain lacking both OmpA and OmpF, which also expressed a modified version of OmpC. After a series of passages, five new host range mutants were isolated. These mutants were now able to use the outer membrane protein OmpX for infection.

Some phages may require the assistance of other membrane proteins for productive infection, which can complicate interpretation of results. One well-established example is the TonB dependence on FhuA to support infection by T1. While T1 appears to be "TonB-dependent," the activity of TonB is required for FhuA function rather than T1 binding to TonB directly. Though these confounding interactions appear to be limited, they can nevertheless make it difficult to understand the exact interactions between some membrane proteins and their phages.

With the renewed interest in phage therapy, phages able to use more than one receptor (e.g., OmpA and OmpC) or more than one type of receptor (e.g., TonB-dependent vs. non-TonB-dependent) are particularly useful. It is less likely that a host will become immune *via* single mutations or deletion of a single gene, thus rendering the phage more "flexible" in terms of its infectivity. Despite this, relatively few phages are known to use more than one receptor – or, if they are able to use more than one receptor, the additional receptor(s) have not yet been identified. This dual-receptor feature is particularly useful for phages and for our use of them in phage therapy, given the ability for phage and bacteria to co-evolve as discussed in the next section.

Ecology and Evolution of Phage-Host Interactions

Bacteria are capable of blocking a successful phage infection at multiple steps of the phage's replication cycle. One key mechanism of phage immunity is to ensure the phage does not gain access to the host at all. To do this, the host can use four main strategies: (1) receptor loss, (2) receptor mutation, (3) receptor blocking or masking, or (4) producing decoys.

The first strategy is an extreme but effective way to eliminate possible phage infection: to reduce the abundance of whatever protein the phage is recognizing, or to stop producing it altogether. This is most often seen in laboratory experiments, where bacteria are already grown in nutrient-rich media at optimal conditions. A classic example is the phage λ receptor LamB, which is required for maltose uptake in the *E. coli* host. In typical laboratory growth media, plenty of other nutrients are available, so the loss of maltose transport does not significantly hinder the growth of the host. In nature, however, the simple loss of a phage receptor may come with tradeoffs. For some pathogenic bacteria, the loss of a phage receptor actually reduces pathogenicity. This has been observed for *Vibrio cholerae* phage ICP2, which utilizes OmpU. Expression of *ompU* is regulated by the transcription factor ToxR, and deletion of the *toxR* gene renders the bacterium avirulent. In 2014, Seed and coworkers isolated strains of *V. cholerae* that were resistant to phage ICP2. Some of these strains contained mutations in either the *ompU* or *toxR* genes. When tested in an animal model, the *ompU* mutant strains showed slightly decreased fitness compared to wild-type *V. cholerae*. Strains containing the mutant *toxR*, however, were severely attenuated and unable to cause disease. The authors showed that these strains also did not express the *ompU* gene. These latter strains were indistinguishable from a strain completely lacking *toxR*. Thus, although the *toxR* mutant strains were resistant to phage ICP2, they were unable to colonize their mammalian host. This type of interaction is of particular interest for phage therapy applications, as a tradeoff between phage resistance and virulence is a "win-win" scenario.

Another example of receptor loss or reduction is that of "phase variation", where the levels of protein vary depending on environmental signals. An example of this is the phage KVP40, which infects *Vibrio anguillarum* *via* OmpK. Depending on the population density of *V. anguillarum*, individuals may up- or down-regulate expression of *ompK*. In dense populations, where many susceptible hosts are growing together, *ompK* is not expressed; however, as the population becomes less dense, the expression of *ompK* increases. While OmpK serves a function for the bacteria, this added "herd immunity" has a beneficial effect for the entire local population of *V. anguillarum*. Similarly, experiments done by Kim and Ryu in 2012 demonstrated that *Salmonella enterica* serovar Typhimurium will modify its LPS if the culture is shaken vigorously during growth. This modification can completely block phage infection, but the loss of this modification during non-shaking conditions will result in the bacteria becoming susceptible to phage infection once more.

Since the interaction between phage and host can be limited to a small region of the receptor protein, it is also possible for hosts to become immune to phage infection by simple mutations. Returning to the phage Sf6 and its host receptor OmpA, Porcek *et al.* demonstrated in 2015 that a change at just one amino acid in the attachment site could reduce phage infection by 80%. Similarly, mutations occurring in the LPS biosynthesis pathway often render the host immune to specific phages. Simple changes in LPS structure, such as an additional sugar group, can reduce phage infection by several orders of magnitude.

Even if the phage receptors themselves do not change, they can be blocked, masked, or sent into the extracellular space as decoys. Receptor access can be reduced by molecules that block them, such as some sugar molecules produced by species of

Pseudomonas. These produce a mucoid layer around the bacteria, preventing the phage from encountering any underlying receptors. Finally, many species of Gram-negative bacteria produce outer membrane vesicles, which are spheres that bleb off the membrane of the bacteria and are released into the surrounding environment. While these vesicles may not carry anything, they do have all components of the bacteria's outer membrane. Thus, phage can bind to the LPS and receptors and initiate an infection process. Instead of infecting a live cell, however, their genomes remain unused inside this decoy host.

If bacteria were always successful in preventing phage infection, this article would not exist. To overcome bacterial strategies of receptor loss, change, blocking, or decoys, the bacteriophages have a similar array to regain access to their hosts. These include: (1) being able to use multiple receptors, as discussed above; (2) targeting conserved regions of receptors; (3) mutations of the receptor-binding proteins, either by small changes or dramatic rearrangements; or (4) using a tail protein that changes conformation depending on which host protein(s) are available. In addition, phages can also use bacterial defense strategies to their benefit and prevent subsequent infection by other phages.

Phages that target conserved regions of receptors generally have a broad host range, as these regions in the membrane protein tend to be conserved due to functional requirements. Thus, they are conserved across many species and genera of bacteria. If the interaction can be modified by a single mutation in the phage's tail protein, this is another way for phages to regain access to their host. Meyer *et al.* showed in 2012 that bacteriophage λ was capable of recognizing a completely new receptor after only eight days of co-culturing the phage with its host in minimal media. The high number of replicates in this study showed that traversing this evolutionary landscape is highly parallel in laboratory settings, meaning that this evolutionary adaptation is highly favorable for the phage. The ability to recognize this new receptor, OmpF, was conferred by as few as four mutations in the phage's J protein, which forms the needle-like tip of the tail. These mutations mapped to the region known to interact with LamB. Since OmpF and LamB have similar global structures, these few point mutations were sufficient to confer favorable interactions between the phage and this new receptor. A more dramatic method is employed by T4 and related phages, which have hypervariable regions of their tail proteins. These can be rearranged or swapped between phages relatively easily, ensuring that at least some phages are not able to access a host if the host receptor protein becomes mutated. These tail fiber domains can allow the phage to use a different receptor or even a related receptor in a new host.

Even more innovative are the phages that can switch receptors depending on what's available in the environment. Some examples are the *Salmonella* phage SP6 and *E. coli* phages DT57C and DT571/2. These phages have V-shaped tailspikes that swivel to bind to whichever host is more prevalent in the environment. Similarly, phi92 has a radial array of at least 3 receptor-binding regions on its tail fibers. This allows the phage to infect both *Salmonella* and *E. coli* – two separate genera of enteric bacteria. Based on our current understanding, this is an unusual feature for most bacteriophages.

Besides recognizing alternate receptors, phage can actually affect receptor structures by producing their own proteins to modify their host's exterior surface. These modifications can occur in either primary or secondary receptor structures. For example, several *Shigella* phages and some *Salmonella* phages produce enzymes that add sugar moieties to the bacterial O-antigen. This O-antigen modification, known as *seroconversion*, can prevent other phages of the same or related species from double-infecting a host cell. This strategy requires the host to produce an O-antigen, which is not the case for all strains of bacteria.

In addition to LPS modifications, a few bacteriophages can encode "shielding proteins", which bind to secondary protein receptors. The related *E. coli* phages EPS7 and T5 each produce a shielding protein that targets a separate Omp. Phage EPS7 utilizes protein BtuB as a secondary receptor, whereas T5 uses FhuA as discussed above. The shielding proteins produced by these phages bind specifically to their own secondary receptors: the EPS7 protein BF23 binds to BtuB and the T5 protein Llp binds to FhuA. Shielding their own receptors specifically likely serves as a superinfection exclusion mechanism to prevent secondary infection by the same phage species. The effects of phage-encoded proteins on the exterior surface of their hosts will likely need to be studied further, especially if phage therapy starts being used to replace or supplement antibiotics.

Relevance of Phage-Receptor Interactions to Phage Therapy

Phage therapy involves the use of bacteriophages to treat bacterial infections and could be a viable strategy to combat drug resistant strains. Even though the use of phages for therapy was explored as early as 1917, very few countries have approved this treatment for infections. One of the key factors contributing to the under-development of phage therapy is the lack of extensive characterization of bacteriophages and their infection process. The ability of bacteria to develop resistance against phages by evolution is another key challenge, and a successful treatment would require more than one kind of bacteriophage. The use of phage cocktails to treat bacterial infections has gained importance recently, as it could be more effective against a diverse set of bacteria and utilize a suite of different receptors. The challenge is to develop a phage treatment protocol with different sets of phages that can be effectively utilized against an evolving population of bacteria.

One of the strategies that bacteria employ to combat phages is to suppress the production of the Omp that a particular phage utilizes, especially if the protein is not critical for growth in the current environment. Knowing which Omp a particular phage uses is critical to address the issue of bacterial resistance to phages. In addition to isolating novel phages that target different receptors, previously-characterized phages that utilize a set of Omps can be obtained by experimental evolution in the laboratory. Phage Ox2, which utilizes OmpA as its secondary receptor, can be evolved in the lab to utilize OmpC or OmpP/X instead of OmpA. Alternatively, screening for phages that can still infect a bacterial strain lacking its receptor can be a mechanism for generating a diverse population and for investigating co-evolutionary dynamics.

A unique approach developed by Turner *et al.* simultaneously utilizes both antibiotic resistance and phage resistance in *Pseudomonas aeruginosa* to neutralize infections. Certain bacteria utilize membrane-based pumps to expel toxic antibiotics – for example, TolC in *E. coli* or the Mex system of *P. aeruginosa*. Turner *et al.* screened for phages that are dependent on the outer membrane-porin M (OprM) for infection, a component of the drug efflux system, and isolated the phage OMKO1. If exposed to a combination of OMKO1 and antibiotics, the bacteria is doomed: it must downregulate or lose the receptor OprM to become resistant to phage OMKO1. Losing OprM will make the bacteria susceptible to antibiotics by rendering the drug efflux pump ineffective. In this study, researchers demonstrated that both laboratory strains and clinical isolates of *P. aeruginosa* that were resistant to OMKO1 phage were sensitive to antibiotic treatment. Confirming this deadly combination, the addition of both phage OMKO1 and tetracycline was more effective in inhibiting growth than the use of tetracycline alone. This combination treatment has been successfully utilized to clear *P. aeruginosa* infection in a patient's aortic graft. Continuing to identify phage outer membrane receptors that also serve as antibiotic efflux pumps in bacteria will greatly advance phage therapeutics and likely enhance the longevity of both types of treatments.

Summary

Our understanding of phage-host interactions has come a long way since the 1950s and is increasingly becoming more direct and precise. Although receptors are now known and characterized for many phages, we are far from saturated. In addition to not having a phage-receptor pair for all – or even most – types of phages or species of bacteria, several confounding factors may complicate our progress. First, although phages that utilize more than one secondary receptor may be most beneficial for phage therapy, it can be difficult to identify which receptors are used and in which order of preference. Second, Omps that require an additional membrane protein, such as the TonB-dependent Omps, can complicate the interpretation of results. Third, since some phages are able to modify their own receptors – and possibly the receptors of other phages – this may have additional effects on the host that we do not yet realize. Investigating these and other relationships involving phage-receptor interactions is critical for understanding bacteriophage biology, phage-host evolution, and for future development of phages for treatments.

Appendix: Methods for Receptor Identification or Characterization

To identify which receptor a phage recognizes, scientists can use genetic or protein-based screens. Genetic screens can be forward or reverse.

In a forward genetic approach, scientists find naturally-occurring mutants based on experimental conditions. For example, lytic phages and hosts can be co-cultured, sometimes in the presence of a mutagen, and any bacteria that survive phage attack would be isolated afterwards. If the surviving colonies “bred true” and were still resistant to the input phage, they would be analyzed further. Any mutations found in these survivors could indicate which genes and proteins are involved in phage susceptibility. This is a classic method, as it is possible to conduct screens for resistant mutants without immediately knowing an organism's genome sequence.

In reverse genetic screens, the sequence of the bacterial genome is known, and scientists can therefore create mutants by making specific bacterial genes nonfunctional and testing the effect of each gene product in the process of phage infection. These screens make use of single gene deletion (SGD) or transposon libraries. These libraries are constructed in populations of bacteria, where each individual in the population contains a deletion or disruption of only one gene. The population is large enough to ensure that every gene in the genome is disrupted. To determine which genes are important for bacteriophage attachment, researchers can systematically test the growth of phage on the thousands of strains within the collection and identify which disrupted gene(s) prevent and/or inhibit phage production. For transposon libraries, each strain has one gene that has been disrupted by the insertion of a transposon, usually covering every gene not required for bacterial survival. A powerful aspect of using a transposon library is that it can identify non-binary effects; for example, it is possible to identify genes that either delay or accelerate the infection process when disrupted by a transposon. The KEIO collection in *E. coli* and SGD library in *S. enterica* sv. Typhimurium have been used to identify many phage receptors and other host factors that are important for phage infection.

Identifying a bacteriophage's secondary receptor can also be done at the protein level. One very direct way to do this is to isolate phage-receptor protein complexes. To do this, researchers let the phage bind to its host, lysing the host, then re-isolating the phage with any host proteins still attached. The separation of phage and whichever host proteins, glycans, or even whole membrane vesicles are still bound can be achieved by several methods: ultracentrifugation (typically using a sucrose or cesium chloride gradient), precipitating the phage by crowding it out of solution (*e.g.*, via polyethylene glycol), or size exclusion filtration. Once the phage-receptor complex is separated from the rest of the sample, the associated proteins or surface glycans can be identified through a variety of biochemical means. If the interactions are transient, chemical treatment can covalently link the phage to its receptor(s). Otherwise, it can be difficult to capture complexes that are stable enough to persist throughout the preparation and treatment of the sample. Another complicating factor is that phages can bind to very complex structures like intact membrane vesicles. Binding to these vesicles means an entire blob of membrane will be associated with the phage. In these vesicles, there will be a number of proteins and surface glycans, so follow-up studies are needed to confirm which of the host products are the true or critical receptor(s).

Once the receptor's identity is known, it is useful to determine the structure of the protein and which regions are important for interaction with the virus. Structural studies can illustrate the function of a given protein and how it might interact with a phage. Both classic and modern structural studies require the receptor to be reasonably pure and stable during the experiment. Many phage receptors are transmembrane or membrane-associated proteins, which can be challenging to work with as discussed in [Table 1](#). There are two main levels of structural studies: atomic/near-atomic resolution, which is useful for looking at fine details; or low resolution, which can indicate the oligomeric state and general secondary or tertiary structure of a protein.

Structures obtained from atomic resolution techniques are extremely detailed and contain information about most, if not all, atoms in the structure.

A classic method to obtain this information is X-ray crystallography. Here, a purified sample is prepared in a way that causes the proteins to become highly ordered and densely packed, forming a solid crystal lattice of repeating subunits. Using X-ray beams, the angles and intensities of the resulting diffraction pattern can produce a three-dimensional picture of the sample's electron density. This describes the positions of all (or most) of the atoms and chemical bonds within the protein. Omp receptors – especially those with a β -barrel fold, as discussed below – are excellent proteins for this method due to their inherent stability. In most cases, stable proteins can be resolved at a high resolution, meaning more detailed analyses can follow.

Crystallography is not the only method to gain information about a protein's structure and/or function. A newer technique to do this is cryo-electron microscopy (cryo-EM). Cryo-EM is a form of transmission electron microscopy where samples are first flash frozen in amorphous, or vitreous ice. These samples are then imaged under cryo temperatures (below -180°C) in an electron microscope to collect 2D images of the proteins. A common "single particle" experiment requires collection of thousands to millions of images of individual proteins. Ideally, the proteins are sitting in the ice in many different orientations so the structure is visible from every angle. Computational algorithms applied to a subset of individual particles are then used to combine the 2D images and reconstruct a 3D model of the proteins. Recent advances in instrumentation, camera design, and the ability to handle big data have led to the cryo-EM "resolution revolution", where single particle cryo-EM studies are approaching the high resolution given by X-ray crystallography. Cryo-EM is especially useful for large, multimeric complexes, which are often a challenge in X-ray crystallography. It is also useful for less stable proteins or for proteins that do not crystallize easily. Despite these advantages, cryo-EM is currently limited by the size of the complex, so it is not possible for all samples. Smaller Omps, especially if they are monomers, are too small to be effectively imaged by cryo-EM. On the other hand, several of the giant viruses and jumbo phages are too big to effectively image while bound to cells or their purified receptors. With the cryo-EM field still evolving rapidly, this may not remain a barrier for long.

Not all Omps or phage-host complexes can be prepared or used for the atomic resolution techniques listed above. Instead, there are lower-resolution experiments that still provide information about the basic structure of a given phage receptor. For example, many phage receptors form a variety of oligomeric states that can be calculated by the molecular mass of the complexes. Different Omps can be found as monomers, trimers, or larger complexes. The oligomeric state of receptor proteins are commonly studied by native gels or chromatography, analytical ultracentrifugation, and native mass spectrometry. Native gels or chromatography can be used to sort protein complexes by mass in their native state, then compared to size standards to determine how many copies are found in each complex. Analytical ultracentrifugation combined with sucrose or cesium chloride gradients will separate complexes of different mass, shape, and/or density. Modifications of this technique can also quantitatively determine the affinity of proteins within multimeric complexes. Finally, native mass spectrometry – a newer and very powerful method – can actually be used to calculate the distribution of each complex type within a population. This allows researchers to determine whether protein complexes are highly dynamic and form many different oligomeric states, or if they are more uniform and predominantly have only one form.

Even if these specialized techniques are not available or practical, there are other methods that use optical measurements like fluorescence. Measuring the intrinsic fluorescence from aromatic amino acids or targeted fluorescence from the addition of certain chemicals are relatively quick and easy methods to determine a protein's tertiary structure. Circular dichroism, which measures differences in absorption of polarized light, is also a common technique to determine whether a protein is largely comprised of α -helices or β -sheets. Both of these optical techniques can be combined with chemical or thermal denaturants to test conditions that promote unfolding of the protein, providing information about the receptor stability. From these types of experiments, scientists can learn the secondary or tertiary structural elements of a protein or its inherent stability alone or in a complex.

Some properties of the phage-receptor binding interactions can be measured *in vitro*, including: binding affinity, kinetics of binding, and genome ejection after receptor docking. These approaches rely on the ability to purify the receptor protein and for the receptor to stay active in test tubes. To measure binding affinity and kinetics, increasingly popular platforms use optical measurements like fluorescence to measure how fast receptors bind to phage particles at varying conditions. For other types of phage receptors such as the primary LPS receptor, hydrolysis by the phage tail draws the phage closer to the cell membrane. Enzyme assays are therefore a popular method that can measure how quickly the phage degrades LPS and how quickly it can reach its secondary receptor. For secondary protein receptors which have no associated enzymatic activity, measuring association and disassociation rates can indicate binding strength between the phage and host protein. Techniques such as surface plasmon resonance (SPR), biolayer interferometry (BLI), and fluorescence anisotropy can all be used for these measurements. All of the aforementioned experiments can be done with whole phage or with purified phage tail proteins that interact with the phage's specific receptor. When used in combination, these techniques can paint a relatively complete picture of how the phage identifies and binds to its host.

Finally, with advances in computational capabilities, *in silico* methods are becoming common and powerful techniques to study biological processes. Computational approaches such as molecular dynamics (MD) can model the complex landscapes of membranes, membrane protein receptors, and complex structures such as LPS. As a virtual microscope, MD simulations describe structural biophysics of and biochemical interactions between all these components which can be used predictively to determine how membrane biophysics changes in different environments.

Which is the best method to use? Each has strengths and weaknesses, as discussed here and summarized in [Table 1](#). Like all science, a combination of experimental approaches more accurately captures the complexities of biology.

Glossary

Caudovirales Order of dsDNA bacteriophages with an external tail structure. Includes the *Podoviridae*, *Siphoviridae* and *Myoviridae*.

Contractile injection system Protein complex related to (and including) the contractile tail apparatus of *Myoviridae*. Also includes the type VI secretion system, R-type pyocins, the antifeeding prophage/*Photorhabdus* virulence cassette and other tailocins.

Myoviridae Bacteriophages with a long, contractile tail.

N-fold symmetric assembly A protein complex comprised of N parts in which these parts are spatially related by a rotational axis of symmetry of order N is called an N-fold symmetric complex (e.g., a complex composed of three polypeptide chains that are related by a threefold is a threefold symmetric complex).

Podoviridae Bacteriophages with a short, non-contractile tail.

Siphoviridae Bacteriophages with a long, non-contractile tail.

Introduction

To replicate, bacterial viruses or (bacterio)phages have to infect their microbial hosts. Unlike eukaryotic viruses, which are usually taken up through endocytosis or membrane fusion, bacteriophages are required to translocate their genome and certain proteins across the host cell envelope. To address this challenge, an overwhelming number of phages use a structure known as a tail. The tail creates a conduit between the phage capsid and host cytoplasm and allows the phage particle to remain attached to the cell surface. Such phages are known as the tailed bacteriophages or *Caudovirales* (Fig. 1). The genome of all *Caudovirales* is a double-stranded DNA molecule, which is packaged into an icosahedral capsid. The proteinaceous tail structure is attached to a special vertex of the capsid through which the DNA is packaged during capsid assembly.

The tail is crucial in the infection process of *Caudovirales*: it is responsible for the initial host recognition and attachment that may include digestion or modification of the cell surface polysaccharides, for the irreversible attachment to the cell, for the degradation of the peptidoglycan, for sensing the “injection signal”, and for the translocation of DNA and proteins into the host. Because of the multitude of challenges that need to be overcome, it is not surprising that these tails are large, multiprotein assemblies of extreme complexity. For example, the tail of bacteriophage T4, one of best studied and more complicated phages, consists of a total of at least twenty different gene products present in varying stoichiometries.

In gram-positive bacteria and archaea, the genome needs to be injected across the only membrane of the cell. In gram-negative bacteria however, both the inner and outer membranes (as well as the peptidoglycan layer) need to be crossed, generating some additional requirements for the tail structures of phages infecting these organisms.

It should be noted that other viruses outside the order of the *Caudovirales*, have been found to have structures that are reminiscent of tails, and are used to inject the genome: e.g., the ssRNA virus MS2, the ssDNA virus ϕ X174, the dsDNA phage PRD1, the algal virus PBCV-1, certain archaeal viruses such as *Acidianus* two-tailed virus (ATV) and some eukaryotic viruses such as Herpes simplex. These viruses are discussed in other chapters of this collection.

Here, we will discuss the function and dynamics of the tail of the *Caudovirales*. We will examine the similarities and differences of all three families belonging to this order and point out specific differences between tails of bacteriophages targeting gram-positive and gram-negative bacteria.

Caudovirales

The order of the *Caudovirales* represents the largest group of bacteriophages, and therefore, of viruses. *Caudovirales* can infect either bacterial or archaeal hosts, suggesting that they share a common ancestor that is as old as the emergence of the bacteria circa

A common evolutionary origin for tailed-bacteriophage functional modules and bacterial machineries. *Microbiology and Molecular Biology Reviews* 75, 423–433.

3.5 billion years ago. The common architecture and sheer complexity of these viruses makes it near impossible to have arisen from convergent evolution.

The tail is attached to a special vertex of the capsid that is occupied not by a capsid protein but by a 12-fold symmetric mushroom- or cone-shaped protein called the head-to-tail connector or portal (**Fig. 1**). Most tails have (mostly) sixfold symmetry, although pseudo-sixfold/true threefold symmetric tails exist. The portal protein is responsible for symmetry adjustment between the tail and the five-fold symmetric vertex of the capsid which houses the portal. During phage particle morphogenesis and prior to tail attachment, the portal protein is part of the phage-encoded machinery that uses ATP to package the DNA genome into the preformed capsid.

Tails can be divided into three different types, and tail morphology has been one of the obvious and widely used characteristics to classify phages. There are bacteriophages with a short, non-contractile tail (*Podoviridae*); with a long, non-contractile tail (*Siphoviridae*) and with a long, contractile tail (*Myoviridae*) (**Fig. 1**). This classification emphasizes host recognition, binding, attachment and genome delivery mechanisms – all the processes that precede host takeover by the phage and production of new phage particles. In that aspect, post-DNA delivery behavior of phages that have different tail morphologies, e.g., P22 and lambda (*Podoviridae* and *Siphoviridae*, respectively), could be more similar to each other than those of the same type, e.g., P2 and T4 (both *Myoviridae*).

Siphoviridae are the most prevalent family of tailed phages (**Fig. 2**). They are characterized by their long tail which is tube-like in appearance. The length of the tail is regulated by a tape measure protein (TMP). *Myoviridae* are also a very common family (**Fig. 3**). They contain a tube that is structurally related to the tube of the *Siphoviridae* and which is also of defined length, controlled by a TMP. However, *Myoviridae* tails are more complex as they also contain a sheath structure wrapped around the tail tube. The high complexity of the sheath, the conservation of the tail sheath protein structure and the fact that *Myoviridae* can be found both in bacteria as well as archaea strongly suggests that *Myoviridae* only evolved once. The *Podoviridae* on the other hand are less prevalent (**Fig. 4**). They only target certain types of bacteria, which suggests that they might have evolved multiple times from the *Siphoviridae* and/or *Myoviridae*.

Organization and Assembly of Long Tails

Certain features of *Siphoviridae* and *Myoviridae* are similar, which is why we discuss them here together. In these phages, the capsid and the tail assemble independently from each other.

Upon completion of DNA packaging, one or two head completion proteins bind to the portal vertex of the capsid making the latter competent for tail attachment. In the absence of tail completion proteins, the DNA can leak from the capsid.

Tail assembly starts from the assembly of its capsid-distant part, which is called the tail tip complex in *Siphoviridae* or the central hub-spike complex in *Myoviridae*. In *Myoviridae*, the central hub-spike complex forms the centerpiece of a roughly planar structure called the baseplate. In both systems, this complex interacts with a “ruler” protein called the TMP, its chaperone, and other

Fig. 2 Schematic representation of the conformational changes in the lactococcal phage P2 baseplate upon adsorption to the host cell wall components. The RBPs interact with the lipoteichoic acids through the host recognition domains and six RBP trimers undergo a 200° downward rotation, enabling them to interact with the host-specific “pellicle” phosphopolysaccharides. chaperones whose conservation and functions are unclear. The TMP determines the eventual length of the tail. The tube is then assembled onto the tail tip/central hub-spike complex, first by binding one or two special tube initiator proteins and then by subsequent binding of multiple copies of the tube protein around the TMP (Figs. 2 and 3). The tube initiator proteins and the tube proteins are hexamers, so the trimeric tail tip/central hub-spike complex contains three-to-six-fold adapter domains. Binding of the tail tube terminator protein to the end of the growing tube completes tube assembly. The central hub protein, tube initiator proteins, tube protein and terminator protein are all structurally and evolutionary related.

Fig. 4 Cryo-EM reconstructions of different phages of the *Podoviridae* family showcasing the diversity in size, tail structure and components. All the phages share a common structural feature in the form of fibers/appendages attached generally to the proximal part of the tail. In the *Siphoviridae*, binding of the tail tube terminator marks the end of tail synthesis. However, in the *Myoviridae*, tube completion is followed by the attachment of the tail sheath. One of the baseplate proteins (gp25 in bacteriophage T4) is homologous to one of the domains of the sheath protein (Fig. 3). It forms an integral part of the baseplate-proximal layer of the sheath and can therefore be thought of as the tail sheath initiator protein. The sheath itself is assembled as a six-start helix with a symmetry matching that of the tube. In the very last step of contractile tail assembly, the tail sheath completion protein binds to the tube terminator and to the last disk of the sheath.

In *Siphoviridae*, the head–tail interface is formed by the head completion proteins and the tail tube terminator. In *Myoviridae*, the head completion proteins instead bind to the tail sheath terminator. In bacteriophage T4, the final step in the assembly is the attachment of the long tail fibers to the tail. However, in some other systems, such as e.g., the R-type pyocin, the tail fiber is required for assembly of the baseplate showing that it acts early in the assembly process.

The Tube

The tube is organized around the TMP. The TMP is mainly α -helical in structure and assembles as a multimer of unknown stoichiometry. Given the long size of the tail, the TMP is likely crucial to transmit the “injection signal” from the tail tip complex to the capsid. It has been shown that the length (in number of amino acids) of the TMP correlates with the length of the tail across different phages. Furthermore, deletion of fragments of the tape-measure protein results in a concomitant shortening of the tail. The TMP likely interacts with both the tail tip complex and the tube terminator protein (Fig. 3). As mentioned previously, structural homology of these proteins positioned at both ends of the tube, as well as for the major tube protein, has been established for both *Myoviridae* and *Siphoviridae*. For bacteriophage T4, a myovirus, the structure of the pseudo-hexameric trimeric hub protein gp27, the two tube initiator proteins gp48 and gp54 (each forming a hexamer), and the tube protein gp19 (forming a tube of hexameric rings) have been determined experimentally. Even though the experimental structure of the tail tube terminator gp3 is unknown, its sequence is similar to that of the tube protein. For the *Siphoviridae* there are also several structures of the tube protein, exemplified by p2 ORF18 (pseudohexameric trimeric hub), p2 ORF15 (hexameric tube initiator protein), the N-terminal domain of bacteriophage λ gpV (major tail protein) and bacteriophage λ gpU (tail terminator protein).

The tube of most *Siphoviridae* phages is rather flexible. In contrast, the tube of bacteriophage T4 (and probably most myoviruses) is rigid, even in the absence of the tail sheath. One exception that has been described however is bacteriophage A511 which has a flexible tail although it is a myovirus.

The Sheath

The tail sheath of *Myoviridae* is a complex and intricate molecular machine. Its initial extended state is a high energy conformation whereas the contracted state found in the particle in the post-injection state is a low energy conformation. The contraction powers a drill-like

motion of the tube that results in breaching the integrity of the cell envelope of the host. The contraction is an irreversible process: this makes it especially important that it is only initiated at the right time, when the bacteriophage is correctly positioned on the cell.

The sheath is assembled starting from the baseplate, and the tube–baseplate complex is a necessary primer for sheath assembly. In T4, the sheath consists of 23 hexameric layers of sheath protein gp18 (six per layer). The extended sheath is a six-start helix, with a rise of 40.6 Å and a rotation of 17.2°, is 240 Å wide and 925 Å long. The symmetry of the sheath repeats the symmetry of the tube. This is an important fact, as it suggests the mechanistic basis for sheath assembly. The tube acts as a template for the assembly of the sheath in the extended, high-energy state: indeed, when gp18 is overexpressed in the absence of the baseplate–tail tube complex, the sheath is assembled into a low-energy state similar to the contracted tail sheath, which is only 420 Å long and 330 Å wide. The rise of the contracted sheath is 16.4 Å, and the rotation is 32.9°.

No atomic structure of an assembled bacteriophage sheath is available, but the structures of the sheath in the extended and contracted state for the related R-type pyocin and the type VI secretion system are known. Sequence similarity shows that the structure of the sheath subunit is conserved in all contractile injection systems, although the size of the subunit varies thanks to additional surface exposed domains in some systems. Also of note is that the sheath subunit of the type VI secretion system is encoded by two sequential genes. Each sheath subunit donates and accepts two long linker arms that interconnect all the subunits into a cylindrical mesh resembling a protective bottle sleeve. The connectivity of this mesh is the same in the extended and contracted state. In the contracted state, the entire mesh is simply widened and twisted. The linker arms of the first layer of the sheath subunits extend into the baseplate (where they interact with a T4 gp25-like protein) whereas the tail sheath terminator protein donates its linker arms to the last layer of the sheath subunits.

Baseplates of Long Contractile Tails

The baseplate is by far the most complex part of the contractile bacteriophage (Fig. 3). The best-characterized baseplate is the one from bacteriophage T4. It is believed that all contractile bacteriophages share a common architecture similar to the one of T4. However, each myophage will have very specific adaptations which are important to infect its host. These especially include enzymes to degrade cell walls and tail fibers to specifically bind cells of choice.

All known contractile tail baseplates are hexameric. They are built up of six “wedges”. In T4, the wedge consists of seven gene products, in different stoichiometries, which assemble in a specific order: gp11, gp10, gp7, gp8, gp6, gp53, and gp25. Once wedge synthesis is complete, the wedges can assemble around the central hub complex, consisting of gp27 (the central hub protein), gp29 (the TMP), gp5 and gp5.4. Gp26 and gp28 likely perform a chaperone function as they are not found in the fully assembled baseplate–tube complex. The formed, high energy baseplate has a “dome” shape. In vitro, in the absence of the central hub complex, the baseplates will assemble in a lower energy “star-shaped” form (see next section). After assembly of the dome-shape baseplate, the tube initiators (gp48 and gp54) can bind, followed by assembly of the tail tube and incorporation of the tail tube terminator as described in the previous section.

A minimal baseplate wedge has been proposed to consist of homologs of the following T4 proteins: gp6, gp7, gp25, gp53, and at least one type of tail fiber protein (usually trimeric). Two chemically identical copies of gp6 interact with gp7 to form a heterotrimer that comprises the main part of the wedge. Starting from the center and moving towards the periphery, the gp6–gp7 heterotrimer consists of a part where the three chains interdigitate or interact extensively (the core bundle and the trifurcation unit) and the part where they go their separate ways (two opposing dimerization domains of gp6 and fiber attachment domain of gp7). Gp25 is positioned at the tip of the core bundle and gp53 is wrapped around the bundle. The trifurcation unit sends the three chains comprising it in three different directions. The dimerization domains of two neighboring wedges interact to link the baseplate into a ring. The fiber attachment domain of gp7 forms a radial protrusion on this ring. The N-terminal part of T4 gp7 (which is upstream of the core bundle domain) also interacts with the tail fibers. However, in simpler baseplates (e.g., in phage P2, phage Mu, the R-type pyocin) but even in some complex baseplates (e.g., of SPO1-like phages), orthologs of gp7 do not contain equivalent N-terminal extensions. To summarize, gp6 has an important role in the circularization of the baseplate and gp7 is crucial for the interaction with the tail fiber network (Fig. 3(B)).

Apart from these conserved baseplate proteins, each bacteriophage has a specific set of tail fibers and other structural proteins and/or adaptations. In the case of T4, gp7 is an extended protein, and together with gp8 and gp9 (a dimer and a trimer, respectively), it makes up the intermediate or less conserved part of the baseplate, which is contracting the tail fiber network. In T4, the tail fiber network consists of two different types of tail fibers: the short and the long tail fibers. The short tail fibers (trimers of gp12) are “curled up” around the periphery of the baseplate and form part of the short tail fiber network, which also consists of two other trimeric proteins (gp10 and gp11). The long tail fibers (which have a stoichiometry $(gp34)_3(gp35)_1(gp36)_3(gp37)_3$) bind to the gp9 trimer. These viral adhesins have a tremendous length (~ 1600 Å) and recognize both LPS as well as the outer membrane protein (OmpC). In the assembled T4 particle, the long tail fibers can interact with the neck protein fibrin (gp wac) when the former are in the retracted state. Upon infection, the long tail fibers need to become extended. This regulation might prevent the inadvertent binding of the tail fibers to the host in conditions that are unfavorable. In vitro, retraction and extension can be controlled by pH, ionic strength, temperature and polyethylene glycol concentration.

During the infection process, it is thought that the binding of the long tail fibers to the cell surface induces a conformational change in the baseplate (going from the high energy, dome-shaped state to the low energy, star-shaped state) which also allows binding of the short tail fibers. Although the precise sequence of events is not clear, the “end state” of this process is structurally well understood from the

Fig. 5 Structure of the complex baseplate of phage T4 in a pre-attachment (from cryo-EM), intermediate (modeled) and a post-host-attachment state (based on cryo-EM). The insets are focused on the central part of the baseplate and demonstrate a release of the tail tube–central spike complex, which remains in a fixed position throughout the transformation. Figure reproduced from Taylor, N.M.I., Prokhorov, N.S., Guerrero-Ferreira, R.C., *et al.*, 2016. Structure of the T4 baseplate and its function in triggering sheath contraction. *Nature* 533, 346–352.

structure of baseplates in the “star-shaped” state (Fig. 5). In this post-attachment-mimicking state, the long tail fibers make extended interactions with the baseplate, especially gp11. The short tail fibers are then extended and can interact with the LPS. This is accompanied by a slight opening of the iris formed by gp6 and gp7 and results in an outward movement of the gp6-gp7 core bundles. As gp25 is attached to the tip of the bundles, it also moves outward, pulling on the sheath, initiating its contraction.

As already alluded to, even though the architecture of the baseplate is universally conserved, adaptation to different hosts results in tail fibers and receptor binding proteins (RBPs) of extreme complexity. In fact, the size and complexity of RBPs dwarf the actual baseplate in many large bacteriophages, e.g., in Twort-like phages (e.g., *Listeria monocytogenes* phage A511, *Staphylococcus aureus* phage ϕ 812) or Vil-like phages (e.g., *Escherichia coli* phage CBA120).

Tail Tip Complex of Long Non-Contractile Tails

The tail tip complex and the adjacent part of the tail in siphophages is similar to the basal part of the tail tube and the baseplate hub of myophages. The tip protein, called Tal (tail-associated lysin) in siphophages, is homologous to T4 gp27 (Fig. 2). The protein that forms the interface between Tal and the rest of the tail is called Dit (distal tail protein). Dit is homologous to the T4 tube initiator protein gp48. The tail fibers are attached directly to this complex. In certain phages infecting *Lactococcus lactis* the RBP network is so extensive that it forms a large planar structure that by analogy with myophages is called a ‘baseplate’. However, this ‘baseplate’ appears to be structurally and evolutionary unrelated to myophage baseplate. In some of these phages (e.g., lactophage p2) the RBPs perform an acrobatic move during attachment to the host cell surface – they rotate by 200° upon binding to the cell surface polysaccharides (Fig. 2). This conformational change is accompanied by opening of the Tal trimer, which allows the TMP to exit the tail. The TMP forms a channel across the cell envelope through which the DNA is translocated into the host cytoplasm. Of note, whether the TMP participates in forming a membrane channel in myophages is unclear.

In the case of the coliphage T5, three L-shaped fibers (pb1) are attached to sides of the baseplate-hub protein (BHP) pb3 and one straight fiber containing a single RBP is attached to its center. Pb3 is the Tal protein of T5, as it adopts the same protein fold as that seen with the BHP (gp27) of the T4 myophage. At the end of the tail tube, a two-domain tail tip protein (TTP) pb9 is located in the upper region of the tail tip cone. X-ray crystallography studies have revealed structural similarities between domain A of pb9 and the N-terminal domains of known Dit proteins, such as those present in the lactophage p2. It has hence been proposed that Dit protein modules are likely to be a conserved structural motif amongst both Gram positive and gram-negative host siphophages. It has also been proposed that pb2 forms the TMP and possesses fusogenic and muralytic activity.

In T5, host recognition occurs via the reversible binding of three L-shaped fibers (pb1) to the O-antigen of the lipopolysaccharide. The irreversible interaction of the RBP (pb5) that forms the tip of the central tail fiber with an outer membrane iron-siderophore receptor FhuA initiates a cascade of conformational changes, leading to the expulsion of TMP which digests the peptidoglycan and perforates the cell membrane. TMP plays a role in signal transduction by initiating the opening of the head-tail connector, which leads to DNA release from the capsid. The TMP likely forms a channel that extends the tail through the periplasm and allows the DNA to reach the host cytoplasm.

Short Non-Contractile Tails: Tube-Like Tail Structure

Bacteriophages belonging to the family *Podoviridae* are characterized by the presence of short non-contractile tails varying in lengths in the range of 10–30 nm (Fig. 4). They are the smallest family in the *Caudovirales*, considering the number of different phages discovered. In podophages, the tail is assembled directly onto the portal protein of the capsid after the DNA packaging is complete. The *Podoviridae* tail is generally comprised of two different proteins – a dodecameric protein that interacts with the portal protein (also called, confusingly, the head-to-tail connector in some phages), and a second hexameric protein which forms the rest of the tail tube.

One of the most extensively studied podophages is the gram-positive *Bacillus* phage ϕ 29 (Fig. 4). In ϕ 29, the tail is approximately 380 Å long. Its portal-proximal part consists of dodecameric gp11 and is called the lower collar. It is a funnel-like structure to which twelve receptor-binding tailspikes (called ‘appendages’ in the ϕ 29 literature) are connected. In another podophage, P22, X-ray crystallography has revealed a dodecameric toroidal gp4 complex (called the ‘head-tail connector’ in the P22 literature) to which six P22 tailspike complexes are attached. Phage RBPs that carry enzymatic domains and thus are stockier in their appearance than fibers in electron microscopy images own their ‘tailspike’ name to the P22 tailspikes as they looked like small spikes attached to the P22 tail. A combination of the location, the stoichiometry and the predicted high α -helical content suggests that gp11 of ϕ 29, gp4 of P22 and the head completion proteins of the long-tailed phages could be evolutionarily related.

The distal part of the ϕ 29 tail tube is thicker than the portal-proximal part. It is called the tail “knob” and is formed by a hexamer of gp9. It plays a key role in the infection process because the distal end of the ϕ 29 tube is blocked by a long loop of gp9 prior to DNA ejection. Interestingly, not only the structure of the gp12 tail knob of the *Streptococcus* podophage C1 is similar, but the tubular domain of ϕ 29 gp9 and C1 gp12 is found in the tail tube, neck and baseplate proteins of myophages and siphophages – such as in the gp27 baseplate hub protein of T4 and in the λ tail tube protein gpV. This is an indication that the tails of all three families of phages (*Myoviridae*, *Siphoviridae* and *Podoviridae*) have evolved from a common ancestor.

The tail tip or distal part of the tail tube typically contains proteins that aid either in digesting the host cell wall, or in host recognition or both. ϕ 29 degrades the *Bacillus* cell wall with the help of an enzyme located at the distal end of its tail knob (gp13), capable of cleaving the polysaccharide backbone and the peptide cross-links of the peptidoglycan layer. In phage P22, a long needle extending outwards from the center of the tail base is constructed by a single trimer of gp26. It has been observed that in addition to making the first contact with the host surface, the N-terminal end of the needle acts as a “plug” and prevents DNA leakage.

The Tailspikes, Tail Fibers and Phage-Host Interaction

As the host receptors continuously evolve, the genes present in the tail fibers, tailspikes or tail appendages are selectively pressured to adapt to the ever-changing target, which can range from peptide sequences to polysaccharide moieties. The thin, long tail fibers are rigid and are flexibly attached to the tail. They scout the cell surface for a specific binding target and initiate adsorption. Tailspike proteins on the other hand are shorter, stubbier and possess enzymatic activity (although the substrates are known only for a subset of tailspikes). Tailspikes digest or modify cell surface polysaccharides, thus irreversibly binding the phage particle to the bacterial surface and allowing the tail tube to reach the cell membrane. This event triggers conformational changes in the phage, leading to the formation of a channel or a pore through which genetic material and proteins located in the capsid can traverse across the bacterial cell wall. The tailspikes or fibers hence play a crucial role in the initial host recognition and subsequently in triggering the transfer of the genome.

There is considerable diversity in terms of length, shape and specific functionality not only in fibers and tailspikes of myo-, siph-, and podophages, but even within each group. The majority of these spikes and fibers are homotrimeric – such as gp12 of ϕ 29 and gp17 of T7. In phages such as ϕ 29, the tailspike appendages recognize and cleave the glucosylated poly-glycerol phosphate teichoic acid by a mechanism similar to that seen in some ribonucleases. In phage C1, the appendages are more tail fiber-like and form a skirt around the tail. These appendages carry a flexible globular domain at their distal end.

The dynamics of phage-host interaction depend on the nature of the bacterial host. Gram-positive and gram-negative bacteria differ in cell wall thickness and components, which have led phages to the adoption of different infection strategies. Gram-positive bacteria lack an outer membrane and phages typically interact with cell wall-associated teichoic acids and other glycopolymers embedded in the thick peptidoglycan layer. They must overcome this physical barrier to reach the cell membrane and deliver their genome into the bacterial host cytoplasm. After the phage has reached the cell membrane, it is thought that there needs to be some protein–membrane fusion event. The archetypal phage ϕ 29 relies on the formation of a cone-shaped structure constructed out of the long loop of gp9 that exits from the tail knob upon genome release. This structure functions as a membrane pore, similar to a hydrophobic fusion peptide, which is found in enveloped eukaryotic viruses and of a membrane-active peptide that is present in non-enveloped viruses. This shared mechanism employed by eukaryotic and prokaryotic viruses is likely a consequence of convergent evolution.

For phages of gram-negative hosts, the DNA needs to cross the peptidoglycan and the inner membrane layers. As discussed above, the tails of podo- and siphophages have to be extended by phage and, possibly, host proteins that connect the tail with the cytoplasm. In myophages, the tail tube crosses the outer membrane and the periplasmic space to contact the cytoplasmic membrane, which is invaginated near the tip of the tube. The involvement of other phage proteins (e.g., the TMP) or host proteins in creating the channel spanning the cytoplasmic membrane is unclear and the tip of the tube might be capable of crossing the membrane.

The outer membrane of gram-negative bacteria is dotted with highly conserved porin proteins that serve as reversible binding sites for phage tail fibers. These fibers are also known to interact with the inner (e.g., fibers of bacteriophage T4) or outer (e.g., fibers of bacteriophage ϕ CTX from the *Myoviridae* family) core of LPS. Phage tail spikes on the other hand recognize and degrade the O-antigen (the polysaccharide part of LPS), which brings the particle closer to the bacterial cell surface, thus enabling the recognition of a second receptor in the outer-membrane, which paves the way for irreversible binding and triggers DNA release upon the proper orientation of the phage particle on the cell surface. A number of phages carry multiple sets of tailspike proteins on the particle which allow them to expand their host range from different bacterial strains to different bacterial species (e.g., phage K1–5 infects *E. coli* K1 and K5, phage SP6 infects different *Salmonella enterica* serogroups, and phage SFP10 infects *S. enterica* and *E. coli* O157:H7).

Phages from the T7 supergroup infect most *E. coli* strains (Fig. 4). The T7 particle contains six trimeric fibers of gp17 attached to the proximal end of the tail tube (to the dodecameric gp11 ring). Even though the other end of the fiber is free, and that part will eventually interact with a cell surface receptor, in the free state of the phage most of the fibers are bound to the capsid. Similar to the more complex T4 fibers and the side fibers of the siphophage T5, the T7 fibers are not straight but are bent roughly in the middle. In fact, the T7 fibers resembles the letter “L”. The rough LPS forming the bacterial outer membrane is the main receptor for T7 fiber binding. This interaction is accomplished by rigid body rotation of the fibers and leads to ejection of the capsid core proteins. The latter form an extension to the tail and connect it to the cytoplasm. The extended tail then acts as the conduit for DNA transfer across the bacterial membranes while also protecting it from periplasmic nucleases.

N4-like bacteriophages usually encode at least two different tailspike/tail fiber proteins with the larger protein directly attached to the phage tail and the smaller protein bound to the longer one (Fig. 4). The shorter tailspike (gp63.1) of the N4-like phage G7C is a deacetylase, and the host recognition of G7C depends not only on the main chain structure of the O-antigen, but on the presence of the acetyl group at a certain position of that particular O-antigen. N4 was the first phage that was shown to contain a large virion-encapsidated RNA polymerase (vRNAP) inside its capsid. This enzyme exits the capsid through the tail during infection and participates in genome transfer. The accumulating body of data shows that many phages contain vRNAPs in their capsids that are delivered (together with the genome) into the host cell cytoplasm where they initiate RNA synthesis, although such phages are usually much larger than N4 (e.g., AR9 and PBS1, giant phages of *Bacillus subtilis*).

Glossary

Beta-structure Structural element of a protein made up of beta-strands (beta-strands are elongated parts of protein chains connected to each other via multiple main-chain hydrogen bonds, they can be parallel or anti-parallel); beta-structured elements can be in the form of beta-hairpins, beta-sheets or beta-barrels, among others.

Lipopolysaccharide (LPS) Cell wall component of Gram-negative bacteria which consist of a lipid A membrane anchor and a carbohydrate extra-cellular part. The carbohydrate part is composed of an inner core, an outer core and the variable O-antigen. Lipopolysaccharide is also known as endotoxin; its toxicity is due to our immune system reacting to them.

Peptidoglycan Bacterial copolymer consisting of carbohydrates and amino acids that forms a mesh-like layer

outside the plasma membrane. It contains alternating residues of beta-(1,4) linked N-acetylglucosamine and N-acetylmuramic acid. A short peptide chain joins N-acetylmuramic acid residues together, leading to a three-dimensional network. Also called murein.

Tail fiber Long, thin receptor-binding proteins or protein complexes attached to the tail of a bacteriophage. A typical example are the six long tail fibers of bacteriophage T4.

Tailspike Shorter, stubby receptor-binding proteins attached to the tail of a bacteriophage. A typical example is the tailspike of bacteriophage P22.

Teichoic acid Bacterial copolymers of glycerol phosphate (or ribitol phosphate) and carbohydrates that are linked to each other through phosphodiester bonds, fortifying the cell wall of Gram-positive bacteria.

Introduction

Tailed bacteriophages, belonging to the *Caudovirales* order ("cauda" is Latin for tail), are formed by an icosahedral or prolate capsid, a neck complex, and a short or long tail (Fig. 1). For some phages, these tails are short (podoviruses), for others they are long and flexible (siphoviruses) and for yet others they are composed of two concentric tubes, of which the outer one is rigid and contractile (myoviruses). Phage tails are very important for correct host recognition and efficient DNA transfer into the bacterium. For phages infecting Gram-negative bacteria, the genome must avoid the periplasmic space, where many nucleases reside. Just before DNA ejection, members of the *Podoviridae* family (like T7 and P22) expel multiple copies of internal capsid proteins, which then assemble into a tube, spanning the cell wall and contacting the cytoplasmic membrane (Fig. 1(e) and (f)). Members of the *Myoviridae* family contract the outer tail sheath, driving the inner tail tube into the cell wall (Fig. 1(c) and (d)). Less is known about the exact infection mechanism for the *Siphoviridae* family, but they may recognize existing membrane-spanning protein complexes and subvert these to promote DNA transfer into the cytoplasm (Fig. 1(a) and (b)).

Before DNA transfer can take place, however, the correct bacterium has to be identified. Bacteriophages recognize exposed structures of the bacterium they are going to infect (Fig. 1(g) and (h)). These structures may be proteins, like flagella, pilins, porins or transporters, or oligosaccharides, like lipo-polysaccharide (LPS) for Gram-negative bacteria and teichoic acid for Gram-positive bacteria. Accurate host cell recognition is essential, because a phage that ejects its genome into the medium or into the wrong cell can't replicate. Phage receptor-binding proteins perform this selection of encountered bacteria. These receptor-binding proteins are usually present in multiple copies. Furthermore, each of these are in general homo-trimeric, i.e., they consist of three identical subunits. The presence of multiple trimeric copies leads to a strong avidity effect, allowing relatively weak individual interactions to contribute to strong binding of the phage.

Bacteriophages may first encounter a potential host cell with their heads instead of their tails and maintaining contact with this bacterium could be useful. Candidates for these head-host interactions are the head fibers of phi29, the immunoglobulin-like domains found in structural proteins of many phages and the Dec protein on the bacteriophage L head. These interactions may allow additional time for the tail fibers or tailspikes to recognize the primary receptor on the cell surface. Alternatively, these head proteins may also serve to maintain phages in an environment where suitable host bacteria may be encountered, for example by binding to intestinal mucus.

Adsorption of the phage tail to the host often takes place in two steps. First, via a reversible interaction with a specific primary receptor on the surface of the target cell and then, irreversibly binding a secondary receptor. The phage proteins that mediate these interactions are usually tailspikes or tail fibers.

Phage receptor-binding proteins can be divided into several classes (Fig. 2). Fibers are long and thin, and sometimes composed of more than one type of protein chain, like in phage T4 (Fig. 2(a)). Their length provides reach, perhaps necessary to bind distant receptors on the bacterial surface. Tailspikes are shorter and stubby and may contain an enzymatic function, helping to digest host capsule polysaccharides and allowing the phage to reach the host cell membrane. An example are the tailspikes of phage P22 (Fig. 2(e)). Atomic structures of phage receptor-binding proteins have revealed new protein folds consisting of mainly beta-sheets with different topologies. Often, the three monomers are intertwined, stabilizing the proteins and explaining their resistance to heat and denaturants.

Fig. 1 Tailed bacteriophages and their infection mechanisms. Schematic drawing of a siphovirus attached to the cell wall (in brown) in pre-infection conformation (a) and in post-infection conformation (b). The capsid wall is colored blue, the DNA yellow, the portal complex red, the sheath dark blue, the baseplate dark brown, the tail fibers green and the spike in orange. Schematic drawing of a myovirus in pre-infection conformation (c) and in post-infection conformation (d). Coloring is as for the siphovirus, with the addition of the tail tube in dark red and the short tail fibers in pink. Schematic drawing of a podovirus in pre-infection conformation (e) and in post-infection conformation (f). The tail tube is colored dark blue and the core proteins are colored dark red. Schematic representations of a typical cell wall of a Gram-negative (g) and of a Gram-positive (h) bacterium are also shown, with the different components labeled (LPS, lipopolysaccharide; OM, outer membrane; IM, inner membrane; WTA, wall teichoic acid; LTA, lipoteichoic acid).

In this article, we will review known structures of tail fibers and tailspikes. Detailed knowledge of these receptor-binding proteins will inform us on their receptor-binding properties and allow us to better understand phage infection. It may also allow site-directed mutation to direct phages to different receptors, or the generation of chimeric receptor-binding proteins for the same purpose. Possible applications are detection and elimination of bacteria and incorporation into protein-based biotechnological devices.

Structures of Bacteriophage Tail Fibers

Although most podoviruses appear to have tailspikes, some have relatively long and thin fibrous appendages (Figs. 2 and 3). Coliphage T7, a well-studied example, has six kinked fibers. The T7 tail fibers are each formed by a parallel homotrimer of gp17. The kinked fibers are comprised of a rather large (when compared to other fibers) amino-terminal tail attachment domain, a thin

Fig. 2 Tailspikes and tail fibers. (a) Bacteriophage T4 (EMDB entry EMD-2774). Tail fiber proteins are shown in blue (proximal tail fiber protein gp34), yellow ("knee" protein gp35), dark green (distal tail fiber protein gp36) and red (distal tail fiber protein gp37). The structures of the C-terminal regions of gp34 and gp37 (ribbon diagrams) are shown in their approximate positions. The baseplate (light blue) contains the six short tail fibers, which are made up of gp12 (one is shown as a ribbon diagrams). The carboxy-terminal part of gp37 (b; PDB entry 2XGF), the carboxy-terminal part of gp34 (c; PDB entry 5NXH) and full-length gp12 (d; from PDB entry 5IV5) are shown as ribbon diagrams. (e) Bacteriophage P22 (EMDB entry EMD-1220). P22 tailspikes (gp9) are in yellow. A close-up of a gp9 trimer with each chain colored differently is also shown (f; PDB entry 2XC1). The *Salmonella* O-antigen receptor (ball representation in red and yellow; from PDB entry 1TYX) is shown bound to one of the chains. Amino- and carboxy-termini are indicated for each protein (Nt and Ct, respectively).

shaft, a flexible kink, and a carboxy-terminal domain that is apparently composed of four nodules. The structure of the distal three nodules is known (Fig. 3(c)). This structure revealed a pyramid domain and a globular carboxy-terminal domain. The trimeric pyramid domain is composed of three interacting beta-strands that become shorter towards the carboxy-terminus, yielding a pointed shape. Each beta-sheet is formed by one beta-strand from the first monomer, followed by five beta-strands from the next monomer and three strands from the third monomer. A short alpha-helical neck connects the pyramid domain to the carboxy-terminal globular domain, which is composed of three beta-sandwiches, one contributed by each of the three gp17 molecules. The gp17 beta-sandwich has a unique topology, although it looks a lot like the beta-sandwich head domain of adenovirus fibers.

The *Salmonella* podovirus epsilon15 has six fibers, each made up of a trimer of gp20. Like the T7 fibers, they have a slender amino-terminal part and a flexible kink, but they have a much thicker and somewhat longer carboxy-terminal part. The carboxy-terminal part consists of a tailspike-shape domain and ends in a flower-like structure with three petals.

The tail of myovirus bacteriophage T4 is the best-studied contractile system. The tail consists of a sheath, an internal tail tube and a baseplate which is situated at the distal end of the tail (Fig. 2(a)). Attached to the baseplate are the fibers. There are six long or side tail fibers which interact with the primary receptor and six short or central tail fibers, which interact with the secondary receptor. The long tail fibers of bacteriophage T4 are kinked structures composed of four different proteins: gp34, gp35, gp36 and gp37. The proximal half-fiber is formed by a parallel homo-trimer of gp34. The amino-terminal end of gp34 is attached to the baseplate, while the carboxy-terminal end interacts with the distal half-fiber, presumably with gp35 and/or gp36. A monomer of gp35 forms the "knee". The distal half-fiber is composed of trimers of gp36 and gp37. The gp36 protein subunit is located at the proximal end of the distal half-fiber, while gp37 makes up the distal part, including the receptor-recognizing tip. The short tail fibers are trimers of gp12.

Fig. 3 Structures of tail fibers. Ribbon diagrams of the distal regions of the T5 fiber (a; PDB entry 4UW7), the T5 fiber with its intramolecular chaperone domain (b; PDB entry 4UW8), the T7 fiber (c; PDB entry: 4A0T), the phage S16 fiber consisting of three chains of gp37 and one chain of gp38 (d; PDB entry 6F45) and the Mu fiber with its chaperones (e; PDB entry 5YVQ). Fiber chains are colored magenta, cyan and orange and their chaperones in light pink, purple and dark yellow. Gp38 of phage S16 is colored green. Amino- and carboxy-termini are indicated for each protein (Nt and Ct, respectively).

For the correct folding of gp12, gp34 and gp37 a molecular chaperone, gp57, is necessary. It is a small protein of 79 residues that lacks aromatic amino acids, cysteines and prolines. In vitro, it adopts different oligomeric states. Another chaperone, gp38, must be present for the correct trimeric assembly of gp37. The molecular bases of the gp38 and gp57 chaperone activities are unclear, but it has been proposed that gp57 functions to keep fiber protein monomers from aggregating non-specifically before folding is completed, while gp38 may bring together the carboxy-terminal ends of gp37 monomers to start the folding process. In the related coliphages T2 and T6, in the *Salmonella* phage S16, and presumably many yet other undiscovered T4-like phages, gp38 plays another role. Instead of being just a chaperone, gp38 stays bound to the end of gp37 and serves as the *de facto* receptor-binding protein.

Structures are known for the carboxy-terminal region of gp34 ([Fig. 2\(c\)](#)) and the receptor-binding needle of gp37 ([Fig. 2\(b\)](#)). The carboxy-terminal part of gp34 is important for folding, which is generally true for viral fiber proteins. Crystal structures of carboxy-terminal parts of gp34 revealed three structural repeats containing three central alpha-helices preceded by intertwined loops. Seven more of these repeats are likely present in the unknown amino-terminal part of the structure. Carboxy-terminal to the repeat region, a short triple-helical region followed by two turns is present. The rest of the structure is a long triple beta-helix, interspersed with three tower domains. The tower domains are formed by three anti-parallel beta-sheets, one contributed by each of the three monomers. The first tower domain is decorated with loops, while the loops of the second tower domain are really short and mainly beta-turns. The last tower domain is extensively decorated, including several short alpha-helices and a long beta-hairpin extending towards the carboxy-terminus.

The carboxy-terminal part of gp37 revealed an elaborately interwoven trimeric structure formed by a globular collar domain (about 45 Å wide, at the bottom in [Fig. 2\(b\)](#)), an elongated needle domain (around 15 Å wide) and a small head domain with a width of around 22 Å (at the top of [Fig. 2\(b\)](#)). Each of the three chains runs from the collar domain to the end of the tip and twists around a neighboring chain before turning back, with both the amino- and carboxy-terminus located near the bottom of the collar domain. In the collar domain, each monomer contains a small beta-sandwich of anti-parallel sheets with an alpha-helix inserted into a loop of the outside beta-sheet. The three inner sheets provide the trimer interactions. Next to the collar domain is a small intertwined region. The carboxy-terminus of each gp37 is folded back into the collar domain, making the needle domain an

insertion into the collar domain, projecting outwards. The needle domain is a 150 Å long six-stranded antiparallel right-handed twisted circular sheet, with each of the chains completing one-and-a-half turns (about 540°) around the fiber axis. In the core of the needle domain, hydrophobic and hydrophilic regions alternate, with the latter forming metal-binding sites. Seven iron ions are coordinated octahedrally by two histidine residues from each chain (six histidines per iron ion). Twenty-six residues from each of the three chains form a compact, interwoven head domain of 22 Å in diameter and 18 Å high. The first fourteen amino acids loop around a neighboring chain; the chain then threads through the loop of a neighbor, before turning back into the needle domain. The head domain, being located at the extreme distal end of the long tail fiber, is likely to play a primary role in receptor binding.

The short tail fibers of bacteriophage T4 are parallel homotrimers of gp12. Morphologically, they consist of an amino-terminal virus-binding region, a long thin shaft domain and a more globular carboxy-terminal receptor-binding domain (Fig. 2(d)). The amino-terminal part of the short tail fiber is made up of a base-plate binding region or domain of unknown structure, followed by several of the repeats also present in gp34 (described above). The repeats are followed by a triple beta-helix domain, which is connected to a collar domain by a short alpha-helical neck. From the collar domain, the globular receptor-binding domain protrudes, just like the needle domain protrudes from the gp37 collar domain. The topology of the carboxy-terminal globular part has a complicated "knitted" fold, in which the three protein chains interact extensively with each other. A metal ion was found to be buried deep inside the carboxy-terminal domain. It is positioned on the threefold axis of the protein and is coordinated by the side chains of two histidines from each of the three chains, like the seven iron ions in the long tail fiber.

The distal carboxy-terminal end of the trimeric *Salmonella* phage S16 gp37 protein forms a triangular beta-prism domain and ends in a short triple beta-helix (Fig. 3(d)). The monomeric gp38 adhesin has a modular design. Its amino-terminal attachment domain binds to the tip of gp37 via a hydrophobic platform, whereas the carboxy-terminal specificity domain determines affinity for the host cell receptor. The small amino-terminal gp37 attachment domain forms a helical bundle of three short alpha-helices, from which three tryptophan residues intercalate into three sites in the gp37 platform. Around the hydrophobic platform, a ring of three-fold symmetric hydrogen bonds completes the stable interface.

The specificity domain contains single beta-helix, from which loops project in the direction away from the phage (Fig. 3(d)). Two of these loops are long and contain glycine-rich motifs. There are ten of these glycine-rich motifs, two in one loop and the remaining eight in the other. These motifs form poly-glycine type II helices that are folded into a packed lattice, forming a PGII-sandwich. Sequence variability between related phages is limited to surface-exposed helices and distal loops that form putative receptor-binding sites.

The structure of the bacteriophage mu fiber (gpS) revealed an alpha-helical shaft, a central domain containing beta-sheet domains (called "tower" domains) and triple beta-helix domain, plus a carboxy-terminal beta-strand domain (Fig. 3(e)). The carboxy-terminal domain is relatively thin, elongated and has distal protruding loops which are postulated to form the receptor-binding site. The amino-terminal phage-binding domain was missing from the structure. Interestingly, upon co-expression, the mu fiber chaperone gpU remained bound to the carboxy-terminal domain of gpS and part of its structure could be resolved. GpU contains two domains, an amino-terminal domain that binds to gpS and a carboxy-terminal domain (only partly visible in the structure) that is presumed to be responsible for chaperone oligomerization; this organization is proposed to be general to gpU-like chaperones. Phage particles with and without gpU are both infectious and both the fiber and the chaperone appear to specifically bind LPS.

The structures of the side tail fibers of other "simple" myoviruses like phage P2 are likely similar to the fiber of phage Mu. This is based on the known structures of the fibers from pyocins R1 and R2, which in turn show sequence homology with the fiber of P2. Both the R1 and R2 fibers contain tower domains, thin shaft domains and a carboxy-terminal lectin-like domain. The shaft domains are composed helix-plus-turn motifs, which intertwine with their counterparts in the trimer. The carboxy-terminal lectin-like domain may be involved in receptor-binding.

Siphoviruses lambda and T5, which infect the Gram-negative bacterium *Escherichia coli*, possess fibers at the bottom and sides of their tail tips. The side tail fiber proteins are involved in recognition of cell surface molecules, while the central fiber proteins play an active role in membrane penetration. No high-resolution structure of a siphovirus central tail fiber has been determined, but structural information on some siphovirus side tail fibers is available. Interestingly, the carboxy-terminal part of the lambda side tail fiber has high sequence identity to the carboxy-terminal part of phage T4 gp37, and thus must also form a collar and needle domain. An extra metal-binding motif suggests that the needle domain of the lambda side tail fiber contains eight instead of seven iron ions. The receptor-binding head domain is not homologous and has probably mutated to bind a different receptor. Both the lambda and T5 side tail fibers need a chaperone for folding, but while the lambda chaperone is a separate protein, the T5 chaperone is intramolecular (see below). Interestingly, the lambda side tail fiber chaperone can functionally substitute for the T4 chaperone required for gp37 assembly, gp38.

Bacteriophage T5 has a flexible, three-fold symmetric tail, to which three L-shaped side tail fibers are attached. These fibers recognize oligo-mannose units on the bacterial cell surface prior to infection and are composed of homotrimers of the pb1 protein. Pb1 has 1396 amino acids, of which the carboxy-terminal 133 residues form a trimeric intra-molecular chaperone that is auto-proteolyzed after correct folding. The structure of a trimer of the preceding residues 970–1263 resembles a bullet, with the walls formed by partially intertwined beta-sheets, conferring stability to the structure (Fig. 3(a)). The topology of the structure is unique to pb1 and the protein inhibits T5 infection by competition. A site-directed mutant (Ser1264 to Ala), in which auto-proteolysis is impeded, revealed the structure of the additional chaperone domain (residues 1263–1396; Fig. 3(b)). It consists of a central trimeric alpha-helical coiled-coil flanked by a mixed alpha-beta domain. Three long beta-hairpin tentacles, one from each chaperone monomer, extend into long curved grooves of the bullet-shaped domain.

Fig. 4 Structures of beta-helical tailspikes. (a) *Salmonella* phage P22 tailspike (PDB entry 2XC1). The amino-terminal phage-binding domain (PBD), the central beta-helical receptor-binding domain (RBD) and the carboxy-terminal interdigitated domain (CTD) are indicated. The three chains are colored green, magenta and cyan. (b) The host recognition apparatus of coliphage CB120, consisting of tailspikes 1 (purple, PDB entry 4OJ5), 2 (green, PDB entry 5W6P), 3 (blue, PDB entry 5W6F) and 4 (brown, PDB entry 5W6H). Domains for which high resolution structures are unknown, but that link the four tailspikes to each other are shown as circles or squares. (c) *Bacillus* phage Phi29 appendix (PDB entry 3SUC). The locations of the linker (D1) that links to the amino-terminal phage-binding domain, the beta-helical domains D2 and D3, and the intramolecular chaperone domain D4 are indicated. Coloring is as in part (a).

High-resolution structures of fibers from bacteriophages that infect Gram-positive bacteria are not yet known. *Bacillus* bacteriophages PBP1 and AR9 have long helical fibers with which they ensnare bacterial flagella. SPO1-like phages (e.g., A511) have fibers that fold back under the baseplate, similarly to the way T4 gp12 does, but whether there are structural similarities remains to be seen.

Structures of Bacteriophage Tailspikes and Other Receptor-Binding Proteins

The first high-resolution tailspike structure to be solved was that of *Salmonella* phage P22 (Fig. 4(a)). In each tailspike, a small trimeric beta-structured amino-terminal domain connects with the rest of the virus. These virus-binding domains are connected by a short alpha-helical coiled-coil linker to a central domain, allowing for some flexibility. The central domain is a trimer of parallel left-handed beta-helices, with each helix containing thirteen complete turns. This beta-helix domain is responsible for carbohydrate binding and cleavage (endorhamnosidase activity). The carboxy-terminal domain of the P22 tailspike consists of interdigitated beta-strands and has been shown to be important for correct protein trimerisation and folding.

Many of the lessons learnt from the P22 tailspike structure have turned out to be general. The parallel beta-helix fold present in other tailspike proteins is the most obvious example of this. This fold appears to be especially suitable for carbohydrate cleavage reactions. A monomeric beta-helix fold was first discovered in the enzyme pectate lyase; bacteriophage tailspikes have adopted the fold for efficient recognition and cleavage of host cell wall polysaccharides. Another general lesson is that folding of tailspikes (and of tail fibers and most other viral receptor-binding proteins) starts at the carboxy-terminus. The carboxy-termini of three monomers come together, sometimes with the help of a chaperone, and folding starts. It might appear to be counterproductive to wait until the protein chain is synthesized completely before folding starts. However, for proteins containing repetitive structural motifs, folding the carboxy-terminal domains first makes out-of-register interactions, which might lead to unproductive misfolding, less likely.

Tailspike structures have also been determined for other phages. The *Salmonella* myovirus Det7 and siphovirus 9NA both contain a tailspike with high sequence identity to the *Salmonella* podovirus P22 tailspike (except for the phage-binding amino-terminal domain). Not surprisingly, the three structures turned out to be very similar, containing the same beta-helix and carboxy-terminal domains.

The *Shigella flexneri* podovirus Sf6 also has a tailspike with a beta-helix domain comprised of 13 complete turns, although its sequence has no homology to the beta-helix of the P22 tailspike. The Sf6 tailspike beta-helices are wound around each other with a slight left-handed twist. At the distal carboxy-terminal end of the tailspike, each monomer forms a beta-sandwich domain. A similar carboxy-terminal beta-sandwich domain is also observed in the *Escherichia coli* podovirus HK620, although, with the domain rotated by about 180° around the trimer axis.

The tailspike of *Pseudomonas* podovirus LKA1 has a beta-barrel insertion domain in its beta-helix, which contributes to the active site. Here, the carboxy-terminal domain is a longitudinal beta-sandwich. A similar longitudinal beta-sandwich is also present in a second tailspike of the aforementioned phage Det7, which in fact has a total of four different tailspikes. In this second Det7 tailspike the beta-sandwich domain has homology to a lectin domain, so apart from a putative role in trimerisation and folding, this carboxy-terminal domain may also help the tailspike bind to the LPS O-antigen.

The myovirus CBA120 also has four tailspikes, attached to the side of the baseplate (Fig. 4(b)). The four tailspikes allow binding to and infection of different hosts. Tailspike 1 recognizes *Salmonella enterica* serovar Minnesota, tailspike 2 *Escherichia coli* O157, tailspike 3 *Escherichia coli* O77 and tailspike 4 *Escherichia coli* O78 strains. All four tailspikes have a central beta-helix domain, followed by a bend and another beta-helix domain at the carboxy-terminus (although the carboxy-terminal beta-helix of tailspike 3 is very small). The central beta-helix domains are involved in receptor-binding, while the carboxy-terminal beta-helix domains may be responsible for correct folding. Tailspike 4 has five small amino-terminal domains with which it attaches to the baseplate, to tailspike 2 and to tailspike 1 (Fig. 4(b)). The amino terminal domain of tailspike 3, in turn, attaches to an amino-terminal domain of tailspike 2.

Examples of podoviruses with multiple tailspikes are *Salmonella* phage SP6, *Escherichia coli* phage G7C and *Klebsiella* phage KP32. Phage SP6 has two tailspikes, recognizing the O-antigens of *Salmonella enterica* serovars Typhimurium and Newport, respectively. The two tailspikes are attached to the phage via an adapter protein. This adapter protein can rotate, locating the correct tailspike into the correct orientation for host recognition and infection.

In the case of coliphage G7C, one tailspike, gp66, binds to the phage, and the second tailspike, gp63, binds to an amino-terminal region of gp66. Gp63 has six domains, of which the first two resemble those of the phage CBA120 tailspike 1. These domains have thus evolved to organize the relative organization of tailspikes in myovirus baseplates and in podovirus tails. Domain 3 is a connector domain, also seen in tailspikes with endosialidase activity (see below). Domain 4 is an esterase domain, and it has been shown that the esterase activity is necessary for infection. Domains 5 and 6 are homologous to non-catalytic carbohydrate binding domains. This is an example of a tailspike without a beta-helix fold.

Klebsiella phage KP32 has a similar organization to coliphage G7C, with one tailspike, gp37, binding to the phage, and the other, gp38, binding to an amino-terminal domain of gp37. The crystal structure of gp38 is known. A flexible amino-terminal region is followed by a catalytic right-handed parallel beta-helix domain, and two non-catalytic carboxy-terminal carbohydrate binding domains.

Each monomer of the trimeric tailspike of the *Acinetobacter baumannii* phage PhiAB6 has a small amino-terminal beta-structured phage-binding domain. This domain is followed by a short alpha-helix and a beta-helical exopolysaccharide cleavage domain. The carboxy-terminal part is formed by a triangular beta-prism, an interdigitated region, another triangular beta-prism and a carboxy-terminal beta-sandwich. Structures of other *Acinetobacter* phage tailspikes have also been solved.

The appendices of the Gram-positive *Bacillus subtilis* phage Phi29 (Fig. 4(c)) also contain parallel left-handed beta-helices. Each appendix has an amino-terminal domain D1 of unknown structure, which is bound to the phage neck. A short triple coiled-coil domain connects the amino-terminal domain to a barrel-shaped domain D2 composed of three parallel left-handed beta-helices. The beta-helices in this domain contain around 24 residues per turn and, like in the P22 tailspike, have inserts of variable lengths that form loops. This domain looks similar to the central domain of P22 tailspike and may thus be involved in receptor-binding. Supporting this is a bound buffer molecule in one of the crystal structures (PDB entry 3GQ8). Carboxy-terminal to this, another thinner and much more regular beta-helix domain D3, with turns that contain only around fifteen residues (without significant inserts), is found. Between the two beta-helical domains, a cyclical swap of the polypeptide chains takes place.

To infect *Escherichia coli* K1, which is surrounded by a polysialic-acid capsule, bacteriophage K1F is equipped with receptor-binding proteins that have an endosialidase activity. These proteins are also trimers but lack the typical beta-helices of conventional tailspikes. Instead, the receptor-binding proteins of phage K1F have an amino-terminal phage-binding domain of largely unknown structure, central beta-propeller and beta-barrel domains and carboxy-terminal beta-prism and triple beta-helix domains (Fig. 5(a)). Endosialidases depend on alpha2,8-glycosidically linked sialic acid oligomers. The beta-barrel domain is where the enzymatic polysialic-acid cleavage reaction takes place.

Interestingly, the phage K1F tailspikes and phage Phi29 appendices have intramolecular chaperones like that of the phage T5 fiber (and were actually structurally analyzed in these phages first). The central parts of chaperones are structurally homologous to each other, although the chaperone from Phi29 (D4 in Fig. 4(c)) is smaller and lacks the carboxy-terminal triple coiled-coil present in the intramolecular chaperones of the K1F tailspike and the T5 fiber.

The well-studied lactococcal phages p2, TP901-1 and Tuc2009 all have large baseplate assemblies, containing arrays of six or 18 trimeric globular receptor-binding proteins. These receptor complexes can bind various saccharidic moieties and likely interact with teichoic or lipoteichoic acid on the cell surface. Although these receptor-binding proteins are different in structure from tail fibers, they still share a trimeric structure and also possess a short region of beta-helix as is seen in tailspike proteins. Interestingly,

Fig. 5 Atypical tailspikes and other receptor-binding proteins. (a) Coliphage K1F endosialidase (PDB entry 3JU4). (b) Receptor-binding protein from staphylococcal phage phi11 (PDB entry 5EFV). (c) Receptor-binding protein of lactococcal phage p2 (PDB entry 1ZRU). (d) Receptor-binding protein of lactococcal phage TP901-1 (PDB entry 3EJC). For each panel, the three protein chains are colored green, magenta and cyan. Domains, amino-termini (Nt) and carboxy-termini (Ct) are indicated, where appropriate.

phage p2 appears to bind to the cell surface using only its receptor-binding proteins, while phage TP901-1 possesses both receptor-binding proteins and a central fiber protein, which may also be involved in cell surface recognition and/or cell-wall degradation. The receptor-binding proteins achieve high-affinity binding through avidity resulting from the large number of receptor-binding proteins displayed on the baseplate.

The receptor-binding protein of lactococcal phage p2 has an amino-terminal shoulder domain, a central neck domain and a globular head domain (Fig. 5(c)). The shoulder domain has a beta-sandwich fold and serves to anchor the protein to the baseplate. The neck domain is a triple-stranded beta-helix, with the three protein chains of the trimer winding around each other. Finally, each monomer of the head domain forms a seven-stranded beta-barrel with the same topology as that of adenovirus and reovirus fiber head domain (and different from the coliphage T7 fiber head domain). The receptor-binding protein of the lactococcal phage TP901-1 has the same head and neck domains as the receptor-binding protein of phage p2, but the shoulder domains are replaced by a parallel bundle of three helices (Fig. 5(d)).

Two staphylococcal phages, phi11 and P68, have been shown to have receptor-binding proteins with very similar structures. This is likely to be another example of horizontal gene transfer between different phage types. In the siphovirus phi11, the protein is folded away into the baseplate, while in the podovirus P68, the protein extends away from the phage. Both structures consist of a long, kinked, three-membered parallel alpha-helical bundle. This stalk domain is followed by a five-bladed propeller domain, which may harbor the receptor-binding site. At the carboxy-terminal end, two tower domains are present, which probably have a role in trimerization and structural stability. Appreciable differences between the two structures are the hinge, which in the phi11 receptor-binding protein (Fig. 5(b)) is more acutely folded, and the presence of an octahedrally coordinated iron ion in the phi11 receptor-binding protein, but which is absent in the P68 receptor-binding protein.

Host Cell Recognition

Cell-surface recognition by bacteriophages is a two-step process. While the two steps of interaction with the cell surface may involve only one type of surface molecule, many phages interact with more than one receptor. The phage T5 tail first interacts non-specifically with the O-antigen of *E. coli* LPS through its L-shaped tail fibers (pb1) and then makes strong specific interactions with

Fig. 6 Structures of bacteriophage receptor-binding proteins in complex with bacterial receptors. (a) *Salmonella* phage P22 tailspike complexed with O-antigen octasaccharide (PDB entry 3TH0). (b) Tailspike protein of Sf6 bacteriophage bound to *Shigella flexneri* O-antigen octasaccharide fragment (PDB entry 4URR). (c) Endosialidase of bacteriophage K1F in complex with oligomeric α -2,8-sialic acid (PDB entry 1V0F). (d) *Lactobacillus* phage 1358 in complex with a bacterial cell wall trisaccharide (PDB entry 4RGA). Approximate locations of active sites for polysaccharide cleavage are shown with asterisks where appropriate. In panels (a), (b) and (d), the receptor-binding proteins are viewed from the side, with the carboxy-terminal ends at the bottom of the figure; in panel (c) the protein is viewed from the bottom, i.e., down from the carboxy-terminal end towards the amino-terminal end.

cell-surface receptor, FhuA, through the central tail fiber, pb5. In an analogous manner, bacteriophage SPP1 binds reversibly to cell-wall teichoic acids and irreversibly to a specific cell surface receptor, YueB.

The tailspikes or fibers mediate initial, reversible, contact of the virion with the target cell, but in general do not trigger DNA release from the virion. The role of primary receptor binding is to speed up infection, facilitating a two-dimensional search on the bacterial surface, rather than a three-dimensional search of a large volume. Once the phage is in the correct orientation and/or a secondary receptor is encountered, irreversible binding takes place. At this point, the phage is committed to DNA transfer into the host. The phage, as a microbiological particle, ceases to exist, but its genetic material will direct the genesis of multiple daughter phages - if the bacterium is a suitable host and does not successfully defend itself by a post-infection mechanism (such as a restriction enzyme or CRISPR-Cas system).

Most of the fibers of podovirus T7 normally point upwards, interacting with the phage head. Occasionally, a detached fiber may bind to the host cell LPS. When this happens, the phage may "walk" over the host cell surface, alternately detaching fibers that recognize the host LPS. When all six fibers are detached and bound to the bacterium, the phage is in the correct orientation for infection, with the short conical tail pointing towards and contacting the bacterial outer membrane. Whether there is a specific secondary receptor interaction between the tail and the membrane or a membrane protein is currently unknown. Core proteins then pass through the tail, forming a protective tube through the periplasm for the phage genome to pass through.

Podovirus P22 tailspikes bind glycans with long grooves along its length. Each of the three monomers has a long groove that binds and cleaves the *Salmonella* O-antigen receptor through endo-rhamnosidase activity (Fig. 6(a)). Other tailspikes, such as that of *Shigella* phage Sf6, have the binding site (and active site) in grooves between monomers, with contributing active site residues from both neighboring monomers for each of the three sites in the trimer (Fig. 6(b)). The O-antigen degradation activity allows the phage to get near the bacterial outer membrane and position itself in the right orientation for infection (with the tail tube pointing towards the cell wall). Apart from these two examples, additional structures for tailspikes in complex with their oligosaccharide receptors have been reported. Furthermore, tailspikes often have additional carbohydrate binding domains, these may help increase the affinity for the bacterial cell wall.

Where bacteria have developed different cell wall structures, phages have adapted to bind and, where necessary, digest these. The endosialidase of bacteriophage K1F is an example of this. Poly- α -2,8-sialic acid binds to the beta-barrel domains of the endosialidase and to the triple beta-helix domain (Fig. 6(c)). Only the former site is thought to be involved in polysaccharide cleavage, with the active site on the surface of the beta-propeller domain of a neighboring monomer (Fig. 6(c)). With regards to the enzymatic reactions, endo-depolymerases appear to be preferred over exo-depolymerases, which prevents bacteria to inhibit their activity by "capping" the polysaccharides.

The siphoviruses lambda and T5 recognize host LPS with their long, L-shaped, tail fibers. The exact receptor for the coliphage lambda long tail fibers has not been determined, but the coliphage T5 long tail fibers binds to α (1,2)-linked oligo-mannose of the O-antigen of O8- and O9-type *Escherichia coli*. Interestingly, it appears that before cleavage of the intramolecular chaperone, the L-shaped fibers of phage T5 do not bind their receptors, suggesting that the long beta-fingers cover up the oligo-mannose binding site. However, it has to be kept in mind that both lambda and T5 can infect perfectly well in the laboratory without their long tail fibers, utilizing only the interaction of the central tail fiber with their secondary receptor proteins LamB and FhuA, respectively, even though the rate of irreversible adsorption of the phage to its host cell is substantially reduced.

Many bacteriophages that infect Gram-positive bacteria are thought to recognize teichoic acid moieties, but, unfortunately, no structures of receptor-binding proteins with teichoic acid analogs have yet been determined. Some Gram-positive bacteria form cell wall structures that cover the teichoic acid layer. An example is *Lactobacillus lactis* strain SMQ388, which forms a polysaccharide cell wall "pellicle" made up of specifically linked N-acetyl-glucosamine and galactose and glucose units. The siphovirus 1358 can recognize this polysaccharide and the structure of the receptor-binding protein in complex with a trisaccharide analog has been determined (Fig. 6(d)). This protein has a structure related to that of the receptor-binding protein of *Lactobacillus* phage p2, with a beta-sandwich shoulder domain and a larger head domain, lacking the triple beta-helical neck.

In the case of the myovirus T4, in adverse conditions for phage multiplication, the long tail fibers are in a retracted conformation, lying against the tail sheath and head of the bacteriophage. In the extended conformation, only the proximal end of the fiber is attached to the baseplate. Primary host cell interaction is mediated by the six long tail fibers. As gp37 is known to interact with the glucosyl- α -1,3-glucose terminus of LPS and protein-saccharide interactions almost always involve stacking of sugar residues onto aromatic amino acid side chains, aromatic surface amino acids are attractive candidates for receptor binding. Basic residues like lysine and arginine may also interact with the LPS phosphate groups. Gp37 may also bind reversibly to the outer membrane protein OmpC. If a certain number of long tail fibers are bound to the host, estimated to be three or four, they initiate a conformational change of the baseplate. In the uncontracted phage, the short tail fibers form a garland around the baseplate, in which the amino-terminal domain, a region forming a kink in the shaft domain and the receptor-binding domain are bound the baseplate. During infection, the conformation of the baseplate changes and only the amino-terminal domain remains bound to the baseplate, releasing the rest of the protein and allowing the receptor-binding domain to strongly bind to the LPS oligosaccharide core. When six of the short tail fibers bind to LPS, the phage becomes effectively bound irreversibly to the host, ready for the extensive conformational changes necessary for DNA transfer. The conformational change of the baseplate triggers contraction of the tail sheath that drives the tail tube through the cell membrane, digesting the peptide glycan layer by the tail lysozyme, and ejection of the phage DNA through the tail tube channel into the bacterial cytoplasm.

Phages are not restricted to having only one type of receptor-binding protein, and several mechanisms to increase the number of hosts that can be infected are known. Phages can carry two or more types of tailspikes that have different target specificities, either of which can function in primary receptor binding. For example, coliphage K1-5 is a T7-like phage that has two different tailspikes in its virion, binding α -polysialic acid (K1) or poly-glucuronic acid-N-acetylglucosamine (K5) capsular polysaccharides. The *Bordetella* phage BPP-1 has a reverse transcriptase mechanism with which it creates sequence variability in the receptor-binding site of its fiber. This variability helps the phage keep up with phase variation of the host, allowing it to evolve fibers that recognize the changed host cell wall. The modular nature of tailspikes and tail fibers favors these gene duplication, domain exchange and mutational events, because changes in the receptor-binding domains do not affect the interaction of the spikes and fibers with the rest of the virion.

Some bacteriophages alter the carboxy-terminal regions of tail fiber proteins by DNA inversion, changing their host range. An example is bacteriophage Mu, where the invertible gene segment is called G, and the corresponding site-specific DNA invertase enzyme is Gin (the gene for Gin maps outside the G-segment). The G-segment starts inside the long tail fiber gene (S) and also contains the tail fiber adapter gene (U) and, in inverted form, the genes U' and S'. U' codes for an alternative tail fiber adapter and S' for an alternative carboxy-terminal end of the long tail fiber. The orientation of the G segment thus determines which carboxy-terminal end of the fiber is expressed and which bacterial hosts can be infected. Mu G(+) phage particles expressing S and U are only infectious for *Escherichia coli*, while Mu G(-) phage particles expressing S' and U' have a wider host range and can also infect *Citrobacter freundii*, *Enterobacter cloacae*, and *Serratia marcescens*.

Conclusion and Perspectives

The increasing occurrence of pathogenic antibiotic-resistant bacteria calls for alternative approaches to combat pathogenic bacteria. Using bacteriophages and their proteins are some of a number of promising strategies. Phages or their endolysin proteins may be used to directly kill, while phage tailspikes and fibers can be used to specifically detect pathogenic bacteria. Enzymatic tailspikes may also be used to weaken their cell walls.

Atomic structures of phage tailspikes and fibers have yielded new protein folds and insights into their stability, their interaction with bacterial receptors and O-antigen degradation mechanisms. These insights have been obtained mainly by X-ray crystallography. The rapid development of cryo-electron microscopy is allowing the structure determination of entire phage tail complexes, although for detailed receptor interactions X-ray crystallography and NMR spectroscopy still have a major role to play.

In general, the genes of receptor-binding proteins are those that show most sequence variability between related bacteriophages. This is presumably the result of adaptation to mutations in the receptor of the phage host, of adaptation to a new receptor, or of adaptation to a new bacterial host strain or species. The fact that receptor-binding proteins protrude from the phage capsid allows for these mutations not to affect phage structure, even if whole domains are replaced. Phage-binding domains of receptor-binding proteins of closely related phages, which do interact with the rest of the virus, usually show more sequence similarity than the receptor-binding domain. In some cases, different phages have very similar receptor-binding proteins. Examples are *Salmonella* phages P22, 9NA and Det7 and the carboxy-terminal domains of the lambda and T4 fibers mentioned before. Where these phages infect the same or a very similar host, horizontal gene transfer between co-infecting phages or an infecting phage and a prophage in the genome is a likely mechanism. For many fibers and tailspikes no sequence similarity is detectable between domains of their receptor-binding

Fig. 7 Schematic drawing of site-directed mutated and chimeric phages. In the top row (a), three phages are shown with site-directed mutations in their tailspikes. These mutations modify the shape of the binding site enabling it to fit different bacterial receptors. In the bottom row, three phages with chimeric tailspikes are shown (b). The carboxy-terminal domains are from other phages with different host ranges.

proteins, but the folds are nevertheless the same, even for phages that infect very different hosts. An example is the tower domain in the fiber protein gp34 of coliphage T4 and in the receptor-binding proteins of phages infecting *Staphylococcus*. These similarities may be the result of convergent evolution of different phages finding the same structural solution independently, or divergent evolution of a phage from which one of the branches adapted to a very different host.

Given the large amounts of phages present in Nature and the rapid evolutionary race with their host bacteria, it is likely more new folds will be discovered for their receptor-binding proteins. Knowledge of these folds will allow the structure, and in favorable cases, receptor-binding properties, of newly discovered genes to be predicted. Experimentally determined and reliably predicted structures will also allow the tailoring of phage tailspikes and fibers to new hosts (Fig. 7). This may be done by site-directed mutation, as has been done for the tail fiber of coliphage T3. Replacing entire domains, i.e., generating chimeric receptor-binding proteins, is another exciting possibility. It is possible that in a relatively near future, a battery of phage receptor-binding proteins, plus a plethora of natural and synthetic bacteriophages, will be available for detection and elimination of most bacterial pathogens.

Glossary

Continuum mechanics theory A theory that considers packaged phage DNA as a uniformly charged rod with a specified persistence length (rigidity) organized in a toroidal spool on a hexagonal lattice.

Contractile tail Myophage tails have an internal tail tube encased in an outer sheath. Only the sheath contracts.

Cryo-electron microscopy/tomography (cryoEM/cryoET) Sometimes referred to as electron cryomicroscopy. In both techniques, aqueous samples on a carbon grid are instantaneously frozen in liquid ethane at -196°C . CryoEM, usually specifically referred to as single particle cryoEM, takes a single picture of thousands of particles, which are different orientations in the liquid film. These images are then computationally combined to generate a 3-D image. CryoET is used for larger samples but has much lower resolution. A series of images are obtained from a single sample at different tilt angles to the electron beam. Computation can then generate a 3-D image of the sample.

Higher resolution structures can subsequently be obtained by combining data from different samples.

DNA-condensing agents Among other compounds, low concentrations of the polyamines spermine and spermidine, and the trivalent cobalt hexammine chloride, condense DNA in solution to densities that approach that in phage heads. PEG and high $[\text{NaCl}]$ also induces condensation to form a similar DNA structure.

Extensible tail Some podophages eject internal proteins from their capsid that functionally extend tail length.

Proton motive force The central aspect of Mitchell's chemiosmotic theory. The pmf has two components: a membrane potential (electrochemical gradient) and a pH gradient across the two sides of the cytoplasmic membrane. The protonophore FCCP (carbonyl cyanide-p-trifluoromethoxyphenylhydrazone) is an aromatic, negatively charged compound that can delocalize the charge of bound protons, enabling proton transfer across lipid bilayers. FCCP collapses both the electrochemical and pH gradients of the cytoplasmic membrane.

Protein Ejection and Trans-Envelope Channel Formation

The first observations relating to how phage genomes enter the infected cell were those of Anderson, who obtained electron micrographs showing that phages adsorbed to cells through their tails (although ϕX174 was known at the time it had not been recognized as being tail-less). The following year the classic Hershey-Chase experiment showed that the majority of ^{32}P -labeled T2 DNA but only a minority of ^{35}S -labeled protein became cell-associated, i.e., Waring blender-resistant, after infection. The Hershey-Chase experiment is often described as proving that DNA is the genetic material; however, that had actually been conclusively demonstrated eight years earlier by Avery *et al.* Their demonstration that highly purified DNA constituted the transforming principle was incontrovertible. However, Avery only made the claim privately that DNA was likely to be the genetic material, possibly because the scientific community at the time was not ready to accept his conclusion. The prevailing feelings are perhaps best reflected in a 1946 Nobel Prize being awarded for the structure of Tobacco Mosaic Virus's protein shell. TMV's RNA genome had not been detected, thus protein "must be" the genetic material. Surprisingly, even though their conclusion was in agreement with Avery's data, the Hershey and Chase paper failed to cite Avery *et al.*

Although simple and elegant, the Hershey-Chase experiment has been grossly over-interpreted. That single experiment showed that blending released 75%–82% of T2 ^{35}S -labeled proteins from infected cells but only 15%–35% of T2 ^{32}P -DNA. The paper also reported that less than 1% of the blender-resistant ^{35}S , but a substantial proportion of the ^{32}P , was found in progeny phage. Several additional experiments were also presented in the paper and all the data, not just the usually cited single experiment, are essential for the solid conclusions Hershey and Chase made. However, their conclusion that "protein [of the infecting virion] has no function in the growth of intracellular phage" requires further qualification.

That conclusion is largely correct if one only considers the phage's major structural proteins, which protect the genetic material from environmental nucleases. In addition, long phage tails usually protect the nucleic acid during its translocation into the host's cytoplasm. However, this often involves ejection of virion proteins into the host cell that can protect the infecting virus's genetic material from well-known periplasmic and sometimes cytoplasmic nucleases. These proteins are all likely to be "blender-resistant" in a Hershey-Chase experiment. It remains a conundrum that, at least when using laboratory hosts and laboratory conditions, the DNA genome of the *Bacillus subtilis* phage SPP1 is transiently exposed to the environment and is nuclease-sensitive during infection. As a final comment on phage proteins entering the infected cell, some phages eject their own RNA polymerase, unequivocally essential for phage development, into the host. Thus, some proteins contained within the infecting virion do indeed have a function during intracellular growth. Examples of this phenomenon will be described throughout this article.

We will utilize the phagocentric term "ejection"; phage proteins and DNA are ejected from the virion during infection. The term is much preferable to its counterpart "injection" because it avoids the misleading implication of phages being thought of as a hypodermic syringe; unlike when using the latter, the volume inside a phage capsid does not change significantly during infection.

Proteins are Ejected into the Host Cell at the Initiation of Infection

Hershey himself first showed that “the germinal substance of bacteriophage T2” was ejected into the infected cell; this was most likely the IP (internal proteins) of T-even phages. T4 IP proteins are non-essential for growth in common laboratory hosts but one has been shown to inhibit a restriction enzyme in a hospital-derived strain. Avoiding host restriction by ejecting internal virion proteins is a strategy used by other phages, including the workhorse *Escherichia coli* transducing phage P1. Another T4 IP is gpAlt, which, among other target proteins, ADP-ribosylates one α -subunit of bacterial RNA polymerase in a process that leads to the preferential transcription from T4 promoters after infection. It is not known if these proteins leave the phage capsid before, concomitant with, or after genome ejection, but if the latter there cannot be a significant delay as they need to function rapidly to promote phage infection.

Recently, some giant phages (defined as possessing a genome $> \sim 230$ kb, compared to the ~ 170 kb T4 genome) have been shown to harbor all the subunits of a bacteria-like multi-subunit RNA polymerase inside their capsid. Growth of the *Pseudomonas aeruginosa* phage ϕ KZ has been demonstrated to be independent of the host transcriptional apparatus. The virion-encapsidated RNA polymerase subunits must therefore be ejected into the cell in order to transcribe the phage genome. Whether enzyme ejection precedes, occurs simultaneously with, or follows genome ejection is not known. It should be noted that proteins ejected into the infected cell cytoplasm in an unfolded (perhaps partially) state have the possibility of being refolded by host chaperones. However, unfolded proteins that have to refold in the cell envelope probably do not have this option. Only limited chaperone activity has been observed in the periplasm, and most ejected proteins likely spontaneously fold into their active conformation.

All long-tailed phages must eject at least one protein into the cell before genome translocation into the cytoplasm can occur. Tail length is controlled and made constant by a protein tape measure that occupies the lumen and extends through most of the tail in mature particles. The lumen of the tail is also used as the conduit for genome ejection, and thus the tape measure protein must be removed in order to allow DNA egress. Although there is not yet any direct experimental evidence, there are suggestions that tape measure proteins may facilitate formation of the channel across the cytoplasmic membrane and allow the phage genome to access the cell cytoplasm. Some tape measure proteins have also been shown to harbor a cell wall-degrading activity; these proteins therefore do have at least one defined function inside the infected cell.

Tail-Less Phages

Microviruses, e.g., ϕ X174 and St-1, which lack any external tail on their isometric capsids, have perhaps the most obvious requirement for proteins to be ejected from the virion before any DNA. The capsid of these phages, like those of the more common dsDNA tailed phages, remains on the infected cell surface after genome ejection. ϕ X174 ejects its gpH protein into the cell in order to allow genome transfer into the cell cytoplasm (Fig. 1). gpH was originally called a pilot protein because it appeared to escort the single-stranded (ssDNA) circular genome into the cell cytoplasm. Several molecules of gpH have now been shown to form a tube, functionally equivalent to a tail, through which the ssDNA is transported. Phage protein synthesis is not required but the activity of host proteins, which convert the ssDNA to supercoiled dsDNA (replicative form, RF), may be necessary for complete genome internalization.

The filamentous (ff) ssDNA phages (f1, fd, M13; *Inoviridae*) were once also described as possessing a pilot protein gp3. However, gp3 mainly functions as an adsorption protein that is brought to the surface of the infected cell as the F pilus retracts. Gp3 then interacts with TolA, an inner membrane-anchored component of several interacting proteins spanning the cell envelope of *E. coli*. The TolQRA protein complex mediates disassembly of the f1 coat protein in the inner membrane (where it is

Fig. 1 ϕ X174 infection pathway. Pathway of ϕ X174 genome ejection. After ϕ X174 adsorbs to the bacterial LPS, one of the gpG spikes (green) dissociates. Dissociation causes conformational changes in the newly exposed capsid proteins that result in the opening of a pore at the attached vertex. The pilot proteins gpH (red) emerge and form a tube across the cell envelope through which the ssDNA genome can pass into the cytoplasm. Adapted from Sun, Y., Roznowski, A.P., Tokuda, J.M., *et al.*, 2017. Structural changes of tailless bacteriophage ϕ X174 during penetration of bacterial cell walls. *Proceedings of the National Academy of Sciences of the United States of America* 114, 13708–13713.

Fig. 2 *PRD1 infection pathway.* After its initial collision with a cellular receptor, PRD1 undergoes random movement over the cell surface, eventually orienting its unique vertex almost perpendicular to the cell surface. De-capping of this vertex triggers reshaping of the internal viral membrane by an osmotic flow from the environment into the cell. Reshaping includes formation of a membrane tube that traverses the cell envelope. Once in the cytoplasm, the tube tip is opened to allow DNA delivery. Reproduced from Peralta, B., Gil-Carton, D., Castaño-Díez, D., *et al*, 2013. Mechanism of membranous tunnelling nanotube formation in viral genome delivery. *PLOS Biology* 11 (9), e1001667.

subsequently reused for progeny phage particles) and the *ff* genome may therefore simply enter the cytoplasm by default. The single-strand replication origin is then utilized by pre-existing host enzymes to create RF DNA before mRNA synthesis is initiated.

Little is also known about genome internalization of the small single-stranded RNA (ssRNA) phages (*Leviviridae* and *Alloleviviridae*), the best known of which are MS2 and Q β , which infect F plasmid-containing bacteria. Similar phages are known to adsorb to other conjugative plasmid pili. The single copy of the maturation protein per particle is essential for infectivity; it is cleaved into two fragments and leaves the virion together with the RNA genome. Surprisingly, at this stage of infection, at least in the laboratory, the genome is sensitive to extrinsic RNases. The final location of the maturation protein fragments after infection is not known; how the genome avoids degradation by the periplasmic enzyme RNase I, and how the RNA crosses the cytoplasmic membrane are also poorly understood processes. However, recent studies of both MS2 and Q β by cryo-electron microscopy (CryoEM) are beginning to reveal more details.

Internalization of double-stranded RNA (dsRNA) phage genomes (*Cystoviridae*) is more akin to animal viruses. These bacteriophages have segmented genomes packaged as a nucleoprotein complex that is inside a protein shell. The latter is surrounded by an external membrane consisting of phospholipids and proteins. The membrane fuses with the outer membrane of the host bacterium, and the nucleocapsid enters the periplasm. An endopeptidase that is exposed on the nucleocapsid surface likely hydrolyzes the cell wall to allow passage across the periplasm. An invagination of the cytoplasmic membrane and intracellular vesicle formation is thought to allow the nucleocapsid to enter the cytoplasm where the protein shell is removed. The remaining nucleoprotein core is then active for RNA-dependent transcription and replication. There is therefore no genome or protein ejection *per se* by this class of phages.

The marine *Pseudoalteromonas* spp. phage PM2 (*Corticoviridae*) has an outer protein capsid underlain by a lipid membrane. This phage is novel not only in its mode of genome entry but also in that no virion protein is known to enter the infected cell. PM2 adsorbs to an unknown outer membrane component(s) that in some way senses the cytoplasmic ATP concentration - and not the proton motive force. If the [ATP] is high, the capsid protein dissociates, exposing the lipid core that then fuses with the outer membrane. If the [ATP] is low, the infection is aborted. Fusion of the lipid core releases the genome into the periplasm where it enters the cytoplasm through a membrane pore likely composed of cellular proteins. Interestingly, Ca⁺⁺ ions are essential, not only to stabilize the outer membrane of the infected cell but also to facilitate localized cell wall hydrolysis by a host-encoded muralytic enzyme.

Although the structure of PM2 is similar to the Tectivirus PRD1, the mode of PRD1 infection is strikingly different (Fig. 2). Receptor recognition by PRD1 triggers structural rearrangements and decapping of a capsid vertex. This allows the internal membrane to form a tube-like structure that penetrates the infected cell envelope, forming a channel for phage genome translocation. A virion protein that is embedded in the tube facilitates localized degradation of the cell wall. The energy for tube extension is provided by the flow of liquid along the osmotic gradient from the environment (growth medium, low osmolarity), through the filled capsid, into the higher osmolarity composition of the periplasm/cytoplasm of the cell. The empty PRD1 capsid remains attached to the cell surface. Genome internalization of the related phage Bam35, which infects Gram-positive bacteria, has also been studied.

Short-Tailed Phages (*Podoviridae*)

Short-tailed phages infecting Gram-negative hosts also obviously require proteins to be ejected from the virion before DNA. The short, stubby tails of podophages are too short to span the cell envelope from their adsorption site on the cell surface. The coliphage T7 was the first podophage observed to eject proteins (E proteins) into the cell. In mature virions these proteins constitute a distinct morphological structure inside the capsid abutting the portal and they are ejected into the cell before the genome. Inside the cell they form a dramatically different structure that extends from the tip of the phage tail through the outer membrane, and across both the periplasm and the cytoplasmic membrane (Fig. 3(A)). This elongated structure comprises the channel for DNA transport into the cell. T7 has therefore been described as having an extensible tail, in contrast to the contractile tail sheath of myophages. Other podophages, e.g., salmonellaphages SP6 and P22 (Fig. 3(B)), have also been shown to have extensible tails. This feature is likely common to this phage morphotype, at least of phages infecting Gram-negative hosts.

Clearly, these ejected proteins, as do the tape measure protein of long-tailed phages, have a defined and essential function in facilitating genome entry into the cytoplasm and thus the subsequent growth of intracellular phage.

A major question remains in understanding how protein ejection is accomplished. Three proteins constitute the T7 extended tail and the process must be tightly coordinated as 12 copies of gp14 localize exclusively to the outer membrane of the infected cell, whereas the eight gp15 and four gp16 molecules function together in spanning the periplasm and the cytoplasmic membrane. T7 gp16 contains the only predicted helical transmembrane domain of the ejected proteins (E proteins), and disrupting that predicted helix abolishes infectivity. It has also been shown to bind membranes *in vitro*. Gp16 is also responsible for the localized enzymatic degradation of the cell wall that facilitates phage genome internalization. However, the structure of packaged gp16 is far too large to exit through the phage portal and tail intact; the four copies of this 144 kDa protein must at least disaggregate and partially unfold during ejection. Gp16 must therefore also spontaneously refold, without the help of energy-dependent chaperonins, to form an active enzyme in the periplasm. A similar argument can be made for the eight copies of the 84 kDa gp15. Gp15 has been shown to bind DNA, and may thus escort the leading end of the phage genome into the infected cell.

T7 is not unique in having three E proteins; those of P22 are also present in multiple copies in the virion. Their ejection is clearly controlled as distinct intermediate extended tail structures have been observed during infection when one E protein is defective. Presumably all copies of each E protein are ejected together and separately from other E proteins. How this is accomplished is unknown. P22 also discards its tail needle after it has penetrated the outer membrane. The needle, as with the central tail fiber of the Siphophages described below, blocks the exit channel for phage genome translocation.

In Gram-negative bacteria, the cell wall is composed of a single layer of peptidoglycan, an open network that allows passage of globular proteins up to 45–50 kDa. As mentioned above for some specific phages, many virions contain a cell wall-degrading activity. Note that this cell wall-degrading activity is distinct from the endolysin that elicits cell lysis at the end of the phage growth cycle. Lysozyme, lytic transglycosylase and endopeptidase (cleaving the cross-links in peptidoglycan) activities have been found as part of structural virion proteins. These must therefore penetrate into the periplasm of the infected cell. In T4 and T7, enzyme activity is not essential for infection when the host bacteria are growing exponentially at or above 30°C. However, as cells approach stationary phase or are growing at low temperature, plaque formation requires enzyme activity. In its absence the phage latent period during growth in liquid is greatly extended. T-even phages release their tail-associated lysozyme into the periplasm where it can diffuse and cause extensive degradation. High multiplicities of infection by T-even phages lead to lysis-from-without, a phenomenon where the newly infected cell immediately lyses without producing progeny. Lysis-from-without is primarily a property of T-even phages; most phages infecting Gram-negative cells that contain virion-associated muralytic enzymes constrain that activity to the infecting particle and thus the cell wall is only degraded at the site of infection. However, cell-wall degrading activity has not been detected in all phage virions: λ and its relative HK022, P22, and ϕ X174 appear not to degrade peptidoglycan during the initiation of infection. It is unknown whether the genome ejection apparatus of these phages can freely pass through the peptidoglycan layer or whether the infecting phage merely waits for the normal turnover of peptidoglycan during cell growth to generate a sufficiently large gap.

The thick cell walls of Gram-positive cells require that virion enzymes degrade either or both peptidoglycan and teichoic acid to allow phage access to the cytoplasmic membrane. Such enzymes are often present on the baseplate or tailspikes of phages. The podophage ϕ 29, for example, hydrolyzes both polymers as it drills its way through the *B. subtilis* cell envelope so that its tail knob protein gp9 can fuse with the cytoplasmic membrane (Fig. 3(C)).

Non-Contractile Long-Tailed Phages (Siphoviridae)

In several long-tailed phages, including λ , T5, and the contractile tailed P2, it has been shown that mature virions have the leading end of the genome extending into lumen of the tail. Linear phage genomes always enter the cell with a fixed polarity. Most phages that have been studied exhibit a first-in (during packaging), last-out (during ejection) strategy. An exception is T4, which uses a first-in, first-out strategy. In either scenario, the end that exits first must be positionally constrained during packaging. Cross-linking studies with long-tailed phages have shown that DNA penetrates the portal channel and can extend into the lumen of the tail. As these phages assemble their tails independently of the capsid and of DNA packaging, the plug that closes the portal channel prior to tail addition must be remodeled or removed in the final assembly steps. Recent cryoEM reconstructions have extended the observation of a genome end in the portal channel to short-tailed phages.

These are significant observations suggesting that triggering of genome ejection may only require conformational changes at the tail tip and, for long-tailed phages, ejection of the tape measure protein. The latter may serve to transduce a signal to head-proximal components to initiate genome ejection. It should also be noted that positioning one end of the genome inside the tail lumen during virion assembly provides a direct and efficient path for DNA ejection; it could be difficult for a free genome end inside the capsid to find the exit channel.

Some early studies of phage genome ejection employed λ . A repeat of the “Hershey-Chase experiment” allowed the same conclusions originally made with T2: the majority of λ proteins could be removed by blending while the majority of DNA remained cell-associated. It was also shown that λ can eject its genome *in vitro* by the simple addition of Mg^{++} and the purified receptor protein LamB. *Shigella sonnei* LamB is effective by itself although *E. coli* LamB also requires the addition of $CHCl_3$ to cause genome ejection. Pioneering *in vitro* studies using electron microscopy of LamB-containing liposomes or crude membranes prepared from λ -infected cells revealed the presence of two distinct complexes: one showed the central gpJ fiber interacting with the outer membrane

Fig. 3 Podophage infection pathways. 3A. T7: After initial adsorption to outer core LPS, T7 is thought to “walk” over the cell surface using a subset of fibers. At a preferred site, “walking” stops and all tail fibers bind, allowing the tail protein gp12 to interact with its receptor in the lipid A-KDO region of LPS. This interaction initiates ejection of the small gp6.7 and gp7.3 proteins into the outer membrane, where they are normally degraded. The internal core proteins gp14, gp15 and gp16 then disassemble and eject into the cell to form a trans-envelope channel from the tip of the tail extending into the cytoplasm. The T7 genome is then translocated into the cell using molecular motors. For more details, see Hu *et al.* 3B. P22: Tailspikes bind to O antigen and by hydrolysis bring the phage to the cell surface. Needle length causes the virion to initially bind at an oblique angle. The virion then reorients, forcing the needle through the outer membrane where it is released. In turn, needle release triggers ejection of the P22 E proteins that form a complete channel for DNA transport extending from the phage baseplate into the cell cytoplasm. For more details, see Wang *et al.* 3C. ϕ 29: ϕ 29 uses its gp12* appendages (called tailspikes in other phages) to adsorb to and then hydrolyze *B. subtilis* wall teichoic acid to bring the virion close to the cell surface. As with P22, the ϕ 29 tail causes the virion to bind obliquely but the gp13 tail tip, which harbors a muralytic activity, can now interact with the cell wall. Continued enzyme activity, both of gp12* and gp13, causes reorientation of the virion and fusion of the gp9 knob protein with the cytoplasmic membrane to form a channel for DNA ejection. For more details, see Farley *et al.* and Xu *et al.* Reproduced from (A) Hu, B., Margolin, W., Molineux, I.J., Liu, J., 2013. The bacteriophage T7 virion undergoes extensive structural remodeling during infection. *Science* 339, 576–579. (B) Wang, C., Tu, J., Liu, J., Molineux, I.J., 2019. (or LamB in the proteoliposome), whereas the second lacked gpJ and the phage tail contacted the membrane surface. In this type II complex, gpJ is sensitive to proteolysis, suggesting that it does not enter a proteoliposome whereas the tape measure gpH*, which is protease-sensitive in free phage, becomes resistant and thus is likely buried in the membrane. This same complex was subsequently shown to form a transmembrane channel, providing the first suggestion that a phage tape measure protein could be ejected from an infecting virion and form a conduit for genome translocation. Unfortunately, perhaps due to methodological limitations of the time, these experiments were not pursued further. The structures of the counterpart proteins to gpJ from the Gram-positive phages SPP1 and p2 are now known; the structures support the idea that the central tail fiber bends out of the way during infection to allow genome release, a feature that may thus be common to many siphophages,

Contractile Long-Tailed Phages

The prototype contractile tailed phage is obviously T4, and we now have a good understanding of the initial steps of infection, particularly for the process of tail tube penetration of the cell envelope (Fig. 4). Other well-studied myophages likely follow a similar pathway, although their baseplate structures are simpler than that of T4 and not all may possess cell wall-degrading activity.

Atomic structures of many T4 proteins have been obtained by X-ray crystallography, and detailed structures of particles both before and after genome ejection *in vitro* have been solved by cryoEM. Furthermore, cryoET has elucidated trans-envelope channel formation for genome ejection *in vivo*. Reversible adsorption of at least three long tail fibers to the cell surface destabilizes the baseplate. This results in the short fibers rotating downwards where they contact the cell and irreversibly bind. In addition, baseplate destabilization allows the tail sheath to spontaneously contract, which drives the inner tail tube through the outer membrane. The tail tube tip then dissociates, releasing the gp5* lysozyme complex into the periplasm. Degradation of the cell wall facilitates further penetration of the tail tube into the cell.

Following tail sheath contraction, the end of the T4 tail tube (now lacking its tip complex) is in the periplasm; despite innumerable cartoons to the contrary it was clearly shown 50 years ago that the tube only extends to the outer leaflet of the cytoplasmic membrane. CryoET now reveals that the membrane blebs outwards in fusing with the tail tube. For DNA to be transported into the cell cytoplasm, the tail tape measure protein must be ejected and it is currently thought that this protein forms the transmembrane channel. Blebbing may then be the simple consequence of the membrane moving towards the fixed end of the tail tube during the fusion process.

Only in myophages has the source of energy been clearly established for changes in protein conformation that occur during infection initiation. The outer sheath of the contractile tailed phages is assembled in a metastable form. When infection is triggered, the sheath spontaneously contracts to a lower energy state structure, one that may be identical to that obtained with purified protein. Although sheath contraction is an essential step during infection, it does not necessarily lead to genome ejection. Sheath contraction can be induced *in vitro* by treating virions with urea but the resulting non-infective virions retain an encapsidated genome. Comparable detailed studies have not been performed with podophages but the structure of purified and complexed T7 gp15 and gp16 bears more resemblance to the extended tail than their structures in the mature virion. Perhaps the internal E proteins of T7 are also assembled in a metastable form.

Factors Affecting Phage Genome Translocation

In 1956, the first quantitative model of ejection hypothesized that simple Brownian motion was responsible for genome ejection, but it was later calculated that the time that would be spent for complete genome ejection by diffusion greatly exceeded the phage latent period. A theoretical proposal, one that was supported using a 10^5 -scale glass model of the T4 virion with nylon thread representing the DNA (!), invoked osmotic pressure inside the phage head as driving the ejection process. However, the most widespread description derives from the first molecular genetics textbook authored by Gunther Stent in 1963: "One may imagine, therefore, that the DNA is packed into the phage head under constraint and forces its own way out through the sheath [*Myoviridae*] after the contraction and "uncorking" reactions of the tail are triggered".

Although usually depicted in textbooks as an instantaneous event, complete internalization of most phage genomes may occupy a substantial part of the latent period. Some specific values are given below, but cryoET studies of infection initiation by several different phages have all visualized partially emptied capsids, where DNA is presumably in the process of entering the cell cytoplasm. Such structures would not be detected if genome transport is extremely fast but there is a caveat to those experiments: all but one study used minicells rather than intact bacteria. Minicells, which are smaller than whole cells and thus allow acquisition of higher resolution structures, have been shown to support growth of some phages. However, minicells lack a chromosome and cannot grow, and additional experiments are therefore underway in which exponentially growing cells are infected. It should be remembered that many of the other assays that have been employed to estimate genome translocation rates are indirect and require interpretations that can also be questioned. For example, genome ejection, once initiated, may continue even at low temperature during disruption of the phage-bacterium complex, and although a genome may be shown to have exited the virion, it may not have entered the cell cytoplasm. A second source of variability lies in the nature of the assay – are populations being measured, where the fastest fraction determines the earliest time recorded, or are single phage-cell complexes being observed?

Fig. 4 *T4* infection pathway. Sequential binding of a subset of long tail fibers (LTF) allows T4 to “walk” over the cell surface. When three or more LTF are simultaneously bound, the strain in each LTF–gp9 baseplate junction triggers conformational changes that releases some STF short tail fibers from the baseplate. The latter, in this transient intermediate, rapidly transitions from its hexagonal to a star configuration, which triggers contraction of the tail sheath and the release and binding of the remaining STF and LTF to the cell. Sheath contraction also pushes the tail tube and needle complex through the outer membrane; this complex then dissociates, allowing the gp5* lysozyme to freely digest the cell wall. The gp27 tail tube, now the distal end of the ejection machinery, contacts the cytoplasmic membrane, which bulges out from its normal plane. Bulging may be caused by ejection of the gp29 tape measure that is thought to make the transmembrane channel for DNA translocation into the cytoplasm. For more details, see Hu *et al.* and Taylor *et al.* Reproduced from Hu, B., Margolin, W., Molineux, I.J., Liu, J., 2015. In addition to the possible presence of DNA phosphate counterions, a function for ion movement has often been proposed during genome ejection. Determining this role has been difficult, in part because ionic strength also affects particle adsorption. Many phages do not adsorb, or do not progress beyond the reversible adsorption step in low ionic strength environments. A very high ionic strength environment is usually also inimical to infection as the initial adsorption steps are governed by electrostatic interactions. In addition, many phages have a specific requirement for Mg^{++} or Ca^{++} , again both for initial adsorption and for the conformational rearrangements of virion proteins necessary to allow genome delivery into the cytoplasm. As examples, Ca^{++} triggers opening of the lactococcal phage p2 baseplate and stabilizes the post-ejection conformation of the distal end of the SPP1 tail *in vitro*. Ca^{++} and/or Mg^{++} are also necessary to stabilize stocks of some, but not all phages.

λ provides an interesting example of the complexities of specific ion requirements for both stability and infection. Free virions and isolated heads are freely permeable to small ions, including the common bacterial polyamines putrescine and spermidine. Isolated tails are slowly (hours) inactivated by Mg^{++} and are usually stored in buffers containing EDTA. Conversely, isolated heads, which have four nucleotides from the single-stranded right end of the genome protruding from the portal, are rapidly inactivated by both EDTA and Mg^{++} due to premature genome release. They are stabilized by putrescine but not by spermidine or spermine, both of which actually markedly increase the rate of genome loss. This is surprising, as spermidine and spermine, unlike

putrescine, are DNA-condensing agents and *a priori* would be expected to stabilize the DNA inside heads. Isolated tails and heads can be mixed *in vitro* to make infective virions that are stable to all polyamines, although Mg^{++} is usually employed for long-term viability. As final complications, λ growth, either by infection or induction of a lysogen, is inhibited in cells grossly deficient in polyamines, but in low (μM) concentrations of Mg^{++} all three common polyamines have been shown to inhibit infection.

Cytoplasmic ions, in particular K^+ , have been shown to leak from cells during the adsorption and genome penetration steps of infection by several phages. It has been suggested that these ion fluxes are responsible for the transient membrane depolarization of the cell that is also associated with the initiation of infection by most phages. Leakage from T5-infected cells occurs only during the two distinct steps of DNA translocation (see below), suggesting that DNA transport and leakage are intimately coupled. However, T5-induced leakage also occurs in cells that have been depolarized, and membrane depolarization can be uncoupled from transport of the SPP1 genome. In addition, K^+ leakage does not require membrane depolarization during PRD1 infection. Ion leakage and/or the transient reduction in membrane potential may simply be a consequence of a phage breaching the cell envelope, an idea first proposed in 1954. Alternatively, membrane depolarization was suggested to be due to protons associating with T1 and T4 DNA as it translocated into the cell. However, in the case of T4, the membrane potential was later shown to be required only for opening or maintaining the channel across the cytoplasmic membrane. In contrast to the above, initiation of infection by T3 or T7 causes neither a reduction in membrane potential nor ion leakage, observations that are currently confined to this phage group. This difference between T7-like and other phages may be the key to understanding their fundamentally different mechanisms of genome ejection.

Transcription-Mediated Genome Internalization In Vivo

The detailed mechanism of DNA translocation from the phage head into the cell cytoplasm has only been established for two phage types; the majority of the T7 and N4 genomes are internalized by transcription. RNA polymerases (RNAP) pull the genome from the phage head into the cell. NTP hydrolysis thus provides the energy both for RNA synthesis and for translocation of the genome out of the phage head into the cytoplasm. Close relatives of these prototype phages likely utilize a similar mechanism of genome internalization, but it has so far only been demonstrated experimentally for the coliphage T3 and the cyanobacteriophage Pf-WMP4.

~ 1 kb of the T7 genome is ejected into the cell at 140 bp/sec ($37^\circ C$) by a process that is consistent with it being enzyme-catalyzed. This reaction then stops and entry of the remainder of the genome requires transcription. It is not known what limits the initial genome internalization process; there is not a specific stopping nucleotide sequence and the ~ 1 kb appears to be a length measurement. Perhaps the leading end of the genome is directly escorted into the cell together with the E proteins gp14, gp15 and gp16. Regardless, promoters for *E. coli* (and T7) RNAP lie on the initial DNA segment that enters the cell, and transcription by the *E. coli* enzyme normally pulls ~ 7 kb of the genome into the cell at 90 bp/sec (Fig. 5). Termination of *E. coli* RNAP-catalyzed transcription at the early terminator T_E is not 100% efficient, and in the absence of phage protein synthesis the *E. coli* enzyme internalizes the entire T7 genome at a constant rate. However, T7 RNAP is encoded on the ~ 7 kb DNA transcribed by *E. coli* RNAP. In normal infections, T7 RNAP is synthesized and the trailing 32 kb of the phage genome is internalized by transcription using the faster phage enzyme. Complete genome internalization takes 5–6 min at $37^\circ C$, about 1/3 of the latent period. Separately measured times of T7 mRNA and late protein syntheses are consistent with the genome internalization rates determined by genome entry experiments.

The transcriptional mode of genome internalization is part of the regulatory process of T7 gene expression. Genes expressed early in infection are the first to enter the cell, whereas late genes, largely encoding structural proteins, enter the cell later and thus can only be expressed after early gene expression. However, this regulation of gene expression is not essential for phage growth. If T7 RNAP is provided in the cell prior to infection, the leftmost T7 promoter (present on the initially ejected ~ 1 kb) is utilized by the exogenously provided T7 RNAP and late mRNAs are synthesized much earlier. Conversely, delaying expression of T7 gene 1 (RNAP) by placing it in the distal 40% of the genome delays genome entry and as a result, synthesis of late RNAs and proteins is delayed.

Mutant virions containing substitutions in two regions of gp16 allow the entire genome to enter the infected cell without the need for transcription. With all substitutions tested, DNA entry occurs at the same constant rate over the entire 40 kb genome without detectable pauses. The substitutions thus appear to inactivate the mechanism that normally stops DNA translocation after the initial ~ 1 kb has been internalized. Importantly, the rate of genome internalization by this mechanism varies with temperature and data can be linearly fitted on an Arrhenius plot, consistent with the process being enzyme-catalyzed. Truncations that remove six or more C-terminal residues of gp16 prevent any DNA from entering the cell cytoplasm; this defect can be suppressed, and viability restored by substitutions affecting gp15. Collapsing the pmf with the protonophore FCCP while the genome is being actively translocated into the cell immediately stops further internalization. Purely by analogy with the F_1F_0 ATP synthase, it was suggested that the ejected gp15 and gp16 proteins formed a rotary pmf-dependent motor that ratchets the genome into the cell base-pair by base-pair. However, it was not determined whether the pmf is directly involved in DNA translocation or in maintenance of the channel across the membrane. RNA polymerase could complete genome internalization (using ATP as its energy source) in the absence of a pmf but only at a much lower rate than in its presence.

In contrast to T7, coliphage N4 virions contain four copies of a phage-specific RNAP (vRNAP). The initial ~ 1 kb of the N4 genome is internalized by transcription but the host RNAP is not involved. The vRNAP must therefore be ejected into the cell cytoplasm before or concomitantly with the leading end of the genome. Extensive genome internalization requires the synthesis of N4 gp1, whose gene is encoded on the initial ~ 1 kb. About 40 kb of the genome is thought to be internalized by this vRNAP-gp1 complex; the remaining ~ 30 kb is catalyzed by transcription using N4 RNAP II and its transcription factor N4 gp2. For many years, N4 was an orphan with no known relatives. However, this phage type now has many examples that infect *Pseudomonas* spp.

Fig. 5 Transcription-mediated T7 genome internalization. T7 ejects ~ 1 kb of its 40 kb genome into the cell using a molecular motor (see text). On the leading end are three strong promoters for host RNA polymerase (RNAP) and a T7 RNAP promoter (not shown). A. Transcription by RNAP from a promoter proceeds normally. B. Transcription continues unabated once RNAP encounters the cell membrane. Rather than the enzyme moving along its template, duplex DNA must now be pulled through the enzyme. The fate of the superhelical turns that are created ahead of the transcription complex is not known, although topoisomerases do not appear to be involved.

The conservation of the two phage-specific RNAPs and their cofactors gp1 and gp2 make it likely that the description of N4 genome internalization applies to the entire group.

Transcription-mediated genome internalization is currently limited to these two phages and their close relatives, and it seems unlikely that many different phage groups will be shown to employ a similar strategy. It is unsuitable for the ~ 50% of tailed phages that package by a headful mechanism (*pac*-type) and therefore have terminally redundant sequences; appropriate promoters for RNAP would not necessarily be correctly located on the varying genome ends of individual virions. The same argument precludes any sequence-specific DNA-binding protein, be it phage- or host-encoded, from facilitating internalization of *pac*-type genomes after only a short segment has entered the cell. Furthermore, some phage genomes that have fixed genome ends (*cos*-type packaging), e.g., λ and T5, are known not to utilize transcription to catalyze genome entry. However, in addition to T7 RNAP and N4 RNAP II, other phage-encoded proteins are known to function in multi-step mechanisms of internalization of *cos*-type genomes.

Non-Transcriptional Genome Internalization In Vivo

The influence of Stent's 1963 textbook, which informed molecular biologists and geneticists of the time – and then their descendants, coupled with the technological inability to experimentally test the idea that a phage genome forces its own way out of the capsid into the cell cytoplasm led to it becoming widely accepted as “fact” for all phages. However, even in 1963 it was known that T5 genome internalization could not be driven by the release of pressure in the capsid arising from the densely packaged DNA. Even more than five decades later, mechanisms of genome translocation from the capsid into the bacterial cell remain unresolved for most phage groups.

Phage T5 genome entry takes place in two distinct steps, called first-step (FST) and second-step transfer (SST). In FST, the first 10 kb of the 121 kb genome enters the cell in ~ 2 min. The transient leakage of cytoplasmic ions and the accompanying decrease in membrane potential stops after FST completion, without a requirement for phage protein synthesis. FST is normally followed by a ~ 5 min pause when the membrane potential is restored and the A1 and A2 genes essential for complete genome internalization, are transcribed and translated. What causes the pause after FST transfer is unknown. The naturally occurring nicks in the T5 genome, the first of which is close to the end of FST, are not required for pausing. However, the DNA sequence surrounding the first nick is replete with direct and inverted repeats that can be imagined to be involved in FST termination; host proteins that bind to the repeats could also have a role.

After synthesis of A1 and A2, SST begins and is associated with a second transient leakage of cytoplasmic ions and a second drop in membrane potential. A2 is a simple dsDNA-binding protein but A1 has many functions that include binding to A2, host membranes, and RNAP. The actual role(s) of A1 and A2 in facilitating SST has not been determined but genome internalization proceeds at a rate of ~ 500 bp/sec and does not require transcription. The assays used to measure T5 genome internalization would not have been adequate to detect pauses in SST *in vivo*, as demonstrated *in vitro*, but if any do occur they are not as pronounced as the termination of FST. The only mutants known to affect SST lie in the A1 and A2 genes. Internalization of the entire 121 kb genome thus occupies ~ 10 min at 37°C . Use of metabolic poisons both to deplete intracellular ATP and to abolish the pmf had no effect on the DNA transport process of either FST or SST. It was thus concluded that genome translocation occurred by passive, or perhaps facilitated, diffusion. Significantly, removal of the capsid after FST (and after synthesis of A1 and A2) still allowed the now naked ~ 110 kb of SST DNA to translocate into the cell cytoplasm and at about the same rate as in a normal infection. These data are obviously inconsistent with the idea that any physical forces associated with DNA densely packaged in phage heads cause genome ejection into the cell cytoplasm.

The $\phi 29$ genome also enters a *B. subtilis* cell in two phases, but unlike T5, the second requires metabolic activity. The first 65% of the genome is ejected into the cytoplasm in what was described as the “push” phase, where internal virion pressure was considered the driving force. Two proteins synthesized early in infection, gp17 and gp16.7, which are coded on the leading part of the genome, are necessary to complete DNA transfer. This second step was called the “pull” phase as energy from the membrane potential was shown to be required, although no detailed mechanism was proposed.

An early study of phage genome entry *in vivo*, again using the Hershey-Chase approach also employed *B. subtilis*. Using an infective center assay, complete internalization of the 140 kb SP82G (*Spounavirinae*, a relative of SPO1) genome took ~ 6 min at 33°C after an initial adsorption step and was independent of phage protein synthesis. Again using blending or sonication to disrupt phage-cell complexes, a complex marker rescue assay showed that the rate of genome internalization is constant: ~ 2 kb/sec at 33°C , ~ 1 kb/sec at 28°C and ~ 0.6 kb/sec at 25°C ; these data were linearly fitted on an Arrhenius plot. No enzymatic mechanism that could catalyze genome internalization was proposed but the constant rate of DNA transfer at a given temperature and the major effect on rate by varying temperature strongly suggests that something other than, or in addition to, physical processes is critical.

λ genome ejection has been followed *in vivo* using single cell-phage complexes. λ virions containing fluorescently stained DNA were observed by microscopy in real time during infection. The gradual reduction in fluorescence of the phage was used to estimate the amount of DNA ejected. Individual phages showed significant variability in the time for complete ejection into the cell with a mean of ~ 5 min, one to two orders of magnitude longer than for *in vitro* ejection into buffer. Pausing events, where genome ejection temporarily halted, were observed in some but not all phage-bacterium complexes. Comparable experiments were also performed using the λ deletion mutant b221, whose genome lacks 22% of the DNA in wild-type phage. Continuum mechanics theory, popular because it is amenable to analytic procedures, considers packaged phage DNA as a uniformly charged rod with a certain persistence length (rigidity) organized in a toroidal spool on a hexagonal lattice. This theory predicts that after 22% of the wild-type genome had entered the cell it should display the same dynamics as the b221 mutant genome. Although *in vitro* DNA ejection dynamics for both genomes are captured by this theory, the *in vivo* results disagree. The experimental data suggest that the ejection dynamics reflect the amount of DNA that has entered the cell, rather than the amount remaining inside the capsid. As currently formulated, continuum mechanics theory cannot explain phage DNA ejection *in vivo*. The experimental results are also inconsistent with two-step models, in which energy stored in the capsid controls ejection of the leading half of the genome with the distal half being internalized by another mechanism (e.g., $\phi 29$). It was suggested that unspecified bacterium-internal processes dominate ejection *in vivo* but it is difficult to relate the observation that the rate of ejection declines after $\sim 50\%$ of the genome is inside the cell, when the bacterial internal forces proposed to dominate the process would be expected to be increasing. This clever *in vivo* assay comes with few assumptions beyond any effects of the intercalating fluorescent dye, but more experimentation is clearly necessary before any mechanistic conclusions can be made.

The observation that T-even capsids contain polyamines sufficient to neutralize 30%–50% of the DNA phosphates, plus the suggestion that electrostatic repulsion between packaged DNA strands could cause genome ejection was generalized in Stent's model that the phage genome was packaged in the capsid under constraint. An alternative idea, perhaps inspired by Mitchell's Nobel-winning chemiosmotic theory, was proposed by Grinius *et al.*: T4 DNA entered the cell by associating with protons (symport) traveling down their electrochemical gradient. It was estimated that the rate of DNA transfer was 10^3 – 10^4 bp/sec and thus complete internalization of the entire ~ 170 kb genome would take a few seconds to ~ 3 min. These data were obtained using variations of the Hershey-Chase experiment; however, the time taken to form the trans-envelope channel was not considered and the major assumption was made that no DNA transport occurred during the separation of phage-cell complexes. The precise rate of T4 genome translocation may therefore be inaccurate but it does appear to be faster than other phage genomes. Furthermore, although the cellular proton motive force, specifically the membrane potential component, was clearly demonstrated to be important it was subsequently shown that the potential was required for trans-membrane channel opening/maintenance rather than DNA transport *per se*. The mechanism of T4 genome ejection therefore remains undetermined.

Models of Phage Genome Ejection *In Vivo*

The dsDNA genome of all phages examined is packaged at near crystalline density, ~ 500 mg/ml. Beginning with Stent's 1963 textbook and the 1969 model building study of T4 genome ejection by Zárybnický, the idea that phage genomes are packaged

under pressure that is subsequently used to drive genome ejection has become commonly accepted. However, almost all the experiments conducted in order to substantiate the idea have been performed *in vitro*. These experiments have focused on inhibiting λ , T5, and ϕ 29 genome ejection by imposing an opposing osmotic pressure with concentrated solutions of polyethylene glycol, PEG 6000–8000.

However, phage genome ejection into cells *in vivo* is fundamentally different from the *in vitro* experiments and cannot be explained by pressure internal to the phage capsid alone. Bacteria maintain an internal osmotic pressure that is necessarily higher than the surrounding environment so that they can enlarge during growth. This excess osmotic pressure is called turgor. Estimates of turgor in Gram-negative cells range from 1 to 5 atmospheres while that in Gram-positive cells is estimated to be ~ 20 atm. In the same way that suspending phage particles in buffered PEG solutions inhibits genome ejection, turgor achieves the same result *in vivo*. Crucially, turgor opposes the ejection of DNA from the phage head into a bacterial cell, and for example, when $\sim 50\%$ of a λ genome has been internalized, the osmotic pressure of the cell cytoplasm and phage capsid was calculated to have been equalized; ejection using only pressure internal to the capsid must therefore stop. Using current continuum mechanics models, a separate process must always operate *in vivo* to complete genome internalization and allow a productive infection. Various theoretical solutions pertaining to the problem have been put forward but none has yet been supported by an actual *in vivo* experiment.

It is worthwhile considering what biophysical characteristics have been established about mature phage particles. Their genomes occupy about half the available volume inside the capsid, the remainder being filled by internal proteins (in some phages only) and buffer. Capsids of the T-even phages are osmotically sensitive; they are slowly permeable to small ions, but polyamines and larger ions are maintained in the capsid at the concentration found in their last host. Osmotic shock-resistant T4 mutants have been isolated that can exchange polyamines by dialysis. Small ions and polyamines contained within most other phage capsids can be readily exchanged by dialysis and some phages are stable in EDTA solutions, at least at low temperature.

If the DNA phosphates of the genome are ionized then ~ 1.5 M monovalent (or their equivalent) counterions must be present. However, the presence of cations that neutralize ionized DNA phosphates in mature virions has recently been questioned; the packaged genomes of P22 and the eukaryotic virus AAV are reported to be in a largely non-ionic state. If confirmed and generalized by extension to other phages, these observations have the potential to profoundly affect long-standing thinking of genome ejection. If the DNA phosphates are actually neutralized as $-P-O-H$, not only is charge repulsion between helices negated but the lack of free counterions necessarily reduces the osmotic pressure inside the virion.

Several observations, together with the long-term stability of most phages in simple buffers, are also not consistent with the view that phages are “pressurized”. Substantial indentations in a mature λ capsid can be made with the cantilever of an atomic force microscope and the deformation is reversible. A reduction in capsid volume with the concomitant expulsion of internal water is therefore tolerated without loss of viability. The packaged highly supercoiled PM2 genome is reported to exert no detectable pressure on the membrane internal to the phage capsid. Remodeling of the PRD1 internal membrane occurs before genome ejection and is driven by exchange of osmolytes between the environment and the infected cell. Proteins have been shown to be mobile inside the T4 head, and the inner body of giant phages is not found at the same location in different virions and is presumably likewise mobile. Several different phage capsids trapped immediately after rupture on an electron microscope grid reveal that the released genome retains the same dimensions as in the intact head. None of these observations is readily reconciled with a high pressure inside the mature capsid. Furthermore, a single P4 genome, only 30% the length of P2 DNA, has been packaged *in vitro* inside a normal-sized P2 head. The calculated internal pressure of such chimeric particles is less than the osmotic pressure inside the bacterial cytoplasm; in these particles internal capsid pressure cannot therefore drive any genome ejection, yet the chimeras were shown to be infective *in vivo*. By contrast, analysis of electron micrographs of the *Staphylococcus aureus* phage P68 revealed that $\sim 2\%$ of particles had ejected an apparently fixed amount of DNA; it is not known what causes DNA release nor what stops the entire P68 genome from exiting those particles. Quantized partial genome ejection *in vitro* has also been observed from T3 virions.

An alternative process, termed the hydrodynamic model for phage genome ejection *in vivo*, posits that extracellular water flows along the osmotic pressure gradient between the environment and the cell cytoplasm, which, because of turgor, must be at a higher osmotic pressure (Fig. 6). In contrast to phage DNA ejection *in vitro*, which contains only two compartments (phage virion and surrounding buffer) with differing osmotic pressures, and where water may enter the phage head only as DNA leaves, phage-infected cells have three compartments (environment, phage head and cell cytoplasm). Each compartment has its own independent osmotic pressure. However, because water transfer is ultimately between the environment and the cytoplasm of the infected cell, the osmotic pressure of the intermediate compartment, the phage head, is thermodynamically unimportant. Water flowing through the phage head and tail into the cytoplasm transports the genome much as logs are moved downstream by a river current. The DNA in the phage tail exerts a drag force on the water flowing past it; in turn, because action and reaction are equal and opposite, the DNA will be moved by the flowing water into the cytoplasm. It is not immediately obvious how to design experiments that would rigorously test the hydrodynamic model for *in vivo* genome ejection. *In vitro* experiments could demonstrate that water flow from a low osmotic pressure environment can transport DNA out of a phage head into a separate compartment of higher osmotic pressure, but such experiments have not yet been reported.

The fundamental differences between the continuum mechanics model for *in vitro* genome ejection and this idea are that the hydrodynamic mechanism involves three compartments: the bacterial cell, the infecting phage, and the environment. The hydrodynamic model thus posits that the energy required in transporting the phage genome lies not inside the capsid but in the environment surrounding the phage and the bacterial cell. Formal mathematical analyses of all the pressures involved in this three-component situation show that if the osmotic pressure of the cell is artificially set equal to that of the environment, the equations and the overall system reduce to be equivalent to the two-body continuum mechanics model. However, in the *in vivo*

Fig. 6 Hydrodynamic model of DNA ejection. (A). There are two osmotic gradients: low-to-high between the growth medium and the phage, and low-to-medium between the growth medium and the cell cytoplasm (turgor). (B). During infection, the two gradients are connected through the phage and only the overall osmotic gradient between the growth medium and the cytoplasm is of thermodynamic importance. When the tail plug (A) is opened during infection (B), water will osmose across the capsid shell and eventually flow into the cell cytoplasm. Hydrodynamic drag on DNA in the tail tube will cause DNA translocation into the cytoplasm. As long as the channel is open and turgor is maintained, continued water flow will completely internalize the genome and any soluble proteins in the virion. Note that this mechanism cannot apply if phage infection (e.g., T7-likes) does not result in transient K^+ -leakage (and thus water import) from cells. See text for more details.

situation where bacterial cells have a higher osmotic pressure, water will flow from the environment, through the phage head and tail, and into the cytoplasm until the channel across the inner membrane is closed. Under the hydrodynamics model, the osmotic pressure inside the capsid will equilibrate with the environment and not with the cell cytoplasm, as posited by the continuum mechanics model. In theory therefore, the entire phage genome can be transported into the cell by a constant force.

DNA is much more condensed in phage capsids than the bacterial chromosome. In order to package a complete genome *in vivo*, the packaging motor must create room in the capsid by displacing water molecules from the DNA. Some of the work expended by the motor is thus used in expelling water across the capsid shell. DNA inside a mature phage head, although it retains its B-form configuration, is therefore dehydrated relative to the bacterial chromosome and especially relative to free DNA in solution. External water molecules thus have a thermodynamic incentive to enter a mature capsid but they cannot do so until infection is triggered and an open channel is created. Opening the channel allows water to flow into the capsid and out through the tail into the cell cytoplasm. DNA that is already inserted into the long tails of siphon- and myo-phages will then be propelled into the cell.

The hydrodynamic model requires that the channel from the capsid into the cell cytoplasm is wide enough for both DNA and water molecules to pass at the same time. This requirement is reasonable, most phage infections are associated with a transient leakage of intracellular cations; if ions can leak out from the cytoplasm through a DNA-filled channel, water molecules should be readily able to enter the same cytoplasm. Significantly for this model of genome ejection, the only phage group (T7-likes) currently known *not* to leak cations at infection initiation, and thus may not be able to use water flow along an osmotic gradient, is known to require molecular motors to transport the entire phage genome into the cell. T7 has presumably found this mode of genome ejection advantageous for its specific life-style.

The hydrodynamic model also provides a potential explanation for how proteins are ejected into the infected cell, a topic that cannot be addressed by DNA-centric continuum mechanics models. Water flow from the environment, through the phage virion and into the bacterium could provide the necessary force for ejection of the tape measure protein that is common to all long-tailed phages. In this case, the initial open channel may extend only into the periplasm, which, however, is iso-osmotic with the cytoplasm. Some tape-measure proteins have actually been suggested to penetrate the cytoplasmic membrane, completing the channel from the phage capsid into the cytoplasm. Water flow could help transport the intra-capsid proteins that form the extended tail of the short-tailed phage P22, and perhaps facilitate formation of the tail-less ϕ X174 ejection tube. Water flow into the cell cytoplasm is also suggested to cause the extended membrane tube formed by PRD1 during infection initiation. By contrast, as concluded from K^+ leakage experiments T7 does not allow water flow; and as previously suggested, the T7 ejected proteins could be assembled into virions in a metastable state and thus contain the intrinsic energy necessary for their ejection into the infected cell.

It seems unlikely that all the ~ 1000 copies of the T-even IP proteins, and internal proteins of other phages packaged at high copy number are similarly metastable. Unless they are transported while bound to the phage genome, such proteins may require

an external force in order to enter the cell. Importantly, however, there is no temporal constraint on when proteins are ejected under the hydrodynamic model: they can leave the capsid before and/or after genome ejection, or if there is adequate space between the internal wall of the tail and DNA, at the same time. The only requirement is that a channel from the phage capsid into the infected cell is open to allow water flow.

Genome and protein ejection from phage virions remains the least understood aspect of phage development. The continued development of cryoEM and cryoET techniques is yielding much needed structural information of the DNA translocation channel before, during, and after genome ejection. Traditional genetics and physiological studies are therefore now beginning to be fitted into a structural environment. Seeing can be believing, but visualizing structures *in situ* is also instructive – it both informs and constrains interpretations of genome ejection mechanistic data that by their very nature may be indirect and can thus be analyzed in different ways. Finally, the development of better kinetic assays that directly measure how much of a phage genome is internalized in the bacterial cytoplasm would certainly increase our understanding of the mechanisms of DNA translocation used by phages.

Glossary

Ejection or E protein Protein that is packaged within the DNA of a phage capsid and upon host infection, exits the capsid with the DNA and enters the host cell.

Prohead Spherical, protein-only precursor form of the capsid.

Introduction

Tailed phages of the *Caudovirales* are considered to be among the most genetically diverse viruses, a trait that is reflected in a diversity of virion structures, and infection mechanisms. As their name suggests, the virions of all tailed phages are comprised of a tail and a head of icosahedral, or similar, symmetry. Tails vary dramatically between the main phage taxa: Members of the *Podoviridae* have short, non-contractile tails; members of the *Siphoviridae* have long, non-contractile tails; and members of the *Myoviridae* have long, doubled, contractile tails. The prime function of the tail is the identification and initiation of infection of a suitable bacterium, usually via baseplate and fiber structures, and then delivery of the genome and capsid ejection proteins, or E proteins, into the host cell.

The major role of the head is to package, protect, and deliver both the double-stranded DNA (dsDNA) genome (~12 to ~500 kb), and, more frequently than previously realized, capsid internal proteins. Phage heads are remarkable for so successfully protecting their DNA and protein cargos, as illustrated by the virions of some phages having been shown to be stable and infectious after decades of storage. In contrast to tail structures across phage families, the icosahedral heads of all tailed phages have shared features due to the fact that the basic head structure is formed by the actions and interactions of only three structurally conserved and essential proteins; the major capsid protein (MCP), the portal protein which forms a structure for DNA entry and egress between the head and tail, and the large terminase protein which actively packages DNA into the head. These proteins' ancestries date back to a primordial virus in existence prior to the split of eukaryotes and prokaryotes.

Many copies of the MCP form a thin (~20 Å), but remarkably strong, protein outer shell. The MCP copy number varies as 60T, where the icosahedral triangulation number, or T number, increases from 1 to more than 50. Increasing capsid T numbers correlate with increased capsid dimensions necessary to house a longer genome, and in some instances, extremely large cargos of internal proteins (see below). The stability of the capsid shell can also in some cases be enhanced by MCP crosslinking or surface decoration proteins. Twelve copies of the portal protein form a turbine-like structure located at one unique capsid vertex. The portal has a number of essential functions, including that it is involved in (1) nucleation of prohead assembly and structure, (2) genome packaging into the prohead, (3) attachment of the tail to the head after the genome has been packaged, and (4) acting as a conduit for capsid internal contents as they exit the capsid into the tail upon infection of the host. The third head protein that is conserved in all tailed phages is the terminase which packages the DNA into the head through the inner channel of the portal. The terminase docks to the portal structure as a multimeric motor complex and hydrolyzes ATP to package, as well as often to measure and cut out one genome's worth of DNA from a multi-genomic, replicated and joined head-to-tail DNA concatemer. The mature genome is packed into the prohead to an extraordinarily high, liquid crystalline density (~500 mg/ml), whether there are also cargo proteins packaged before the DNA. In tailed phages, the terminase protein(s) generally dissociate from the portal after packaging and are not part of the mature virion.

Inside the MCP shell, in addition to the highly condensed genome, many phages have internal proteins. The existence of these internal head proteins illustrates beautifully the remarkable diversity that exists between different phages, as internal protein content can vary in sequence, length, copy number, location, and function in the capsid. The existence of internal proteins also highlights the fact that genome packaging occurs successfully in spite of their diversity which results in numerous final internal capsid conditions/states. However, although in every case studied these internal proteins are packaged into the prohead before the DNA, exactly how these proteins impact prohead structure and assembly, DNA packaging, head stability and DNA ejection is incompletely understood for most phages. The presence of internal proteins in different phages also raises the question of: Why are they there? Since, with the exception of a handful of model phages, the knowledge of internal head protein function(s) is limited. Based on knowledge acquired from model phages, such as T7, N4, P22, P1 and T4, there is an expectation that proteins packaged within the capsid outer shell are ejected into the host cell at the time of infection along with the DNA and have roles in host takeover. Consequently, internal head proteins in tailed phages are often referred to as ejection, or E proteins, and in this review we

Fig. 1 Tailed phages whose capsids have Ejection, or E, proteins packaged within their DNA that have a diversity of functions (if known). All example phages infect Gram negative bacteria, but there are also phages that infect Gram positive bacteria that have E proteins.

will use both terms interchangeably, while acknowledging that the ejection status for many such proteins requires experimental confirmation.

We previously delineated tailed phage heads into four subcategories based on the amount and location of E proteins within them (see [Black and Thomas, 2012](#)). Continued research has led us to modify slightly these categories into the following: (1) Capsids that contain only packaged DNA and no, or very few, proteins within them; (2) Capsids that contain a relatively small number (<50) of E proteins that have a specific locale within the capsid; (3) Capsids that contain many (over one-thousand) E proteins embedded within the DNA in no identified order; and (4) Capsids that have a large mass of co-localized E proteins that occupy an appreciable fraction of the inner capsid volume, sometimes in a structure with a defined shape and volume (see [Fig. 1](#) for examples). We note that this categorization of E proteins is simply for ease of discussion, and has no taxonomic or functional basis. Examples of each of these categories of E proteins can be found in different phage families. Conversely, some phages, such as T4, have different classes of E proteins, with different functions, locations and/or abundances of each. All these E proteins, regardless of their structure and locales in the capsid, are able to exit the capsid through the narrow (~30 Å diameter) channel in the center of the portal complex and then must pass through the tail structure of their respective virion [sometimes a long (≥1000 Å), narrow (~30 Å diameter) structure!] for delivery to their bacterial target. That target is dependent upon the E protein's function, for some it is the host outer membrane (e.g., the podoviral core structures discussed below), whereas for others it is the host cytoplasm (e.g., the T4 internal proteins). It should also be noted that all icosahedral phage DNAs in capsids have small molecule counterions, such as polyamines and divalent cations, to neutralize the highly negatively charged DNA phosphodiester backbone; as these molecules likely have no specific biological phage function they will not be discussed as a part of this review.

In this review, we will summarize the major features and functions, where known, of examples of phages whose E proteins fall into the different categories listed above ([Fig. 1](#)). While these examples are mostly from a limited number of extremely well-characterized phages, they serve to demonstrate the eclectic nature of E proteins and their functions. In addition, we will include examples from recent research that hint at the there being a virtual smorgasbord of E proteins in the virosphere, and finish with a discussion on some of the most pressing questions raised by the existence of E proteins.

Tailed Phage Capsids With Low Numbers of E Proteins in Specific Locales

Numbers of unrelated phages have been shown to contain small numbers of E proteins (<50) within their capsids that have specific locales within the densely packaged DNA, often close to the portal structure. Some low copy number E proteins are highly organized into structures consisting of multiple proteins, whereas others may be present as just a handful, or one or two copies, of a single localized protein. Despite their generally low copy number relative to the highly abundant E proteins present in some other phage types (see below), characterization of a relatively small number of examples has illustrated a remarkable range of

functions (numbers are apparently multi-functional), from promoting phage replication (often at the transcriptional level) to the manipulation and modification of cellular structures and molecules to allow or enhance infection. Based on this, it is not surprising that many of these low abundance E proteins have been shown to be essential.

Low copy number E proteins with specific locales in the capsid

Numbers of E proteins are not thought to be part of a specific structure but nonetheless have specific locales within the capsid, typically in close proximity to the portal complex. Examples of localized internal proteins are found in *E. coli* phages N4 and T4, and *Bacillus* phages Phi29 and SPP1. Despite having similar locales, these localized inner capsid proteins have a remarkably eclectic set of functions and several of them are apparently multi-functional. One localized protein that stands out for its unusualness is the virion RNA polymerase (vRNAP) gp50 of the podovirus N4 which was among the first phage E proteins discovered (see Lenneman and Rothman-Denes, 2015). This enzyme is essential; transcribing early genes from atypical promoters containing hairpin/stem structures whose formation is assisted by host proteins (*E. coli* DNA gyrase and single-stranded DNA-binding protein). The single-subunit gp50 is surprisingly large (~380 kDa) relative to its homologs in mitochondria and other phages (e.g., the T7 gp1 RNAP, which is not an E protein, is ~99 kDa). In addition to the central domain of gp50 that is responsible for RNAP activity, the enzyme has a C-terminal domain that targets the vRNAP into the head and an N-terminal domain that is required for the ejection of the first 500 bp of the genome. Only about four copies of the vRNAP are present in each N4 virion and cryo-EM comparison of wild-type versus gp50-minus mutants indicated that the vRNAP is located at the base of an inner protein core, close above the internal entrance to the portal channel. Considering its molecular weight, it is remarkable this vRNAP can pass through the portal channel and other structures to enter the cell.

The myovirus T4 also has two low abundance E proteins, Alt and gp2, whose positions within the capsid are localized. Alt is a large protein (~75 kDa) which ADP-ribosylates host RNAP subunits, and a number of other host proteins, e.g., MazF toxin (see Alawneh *et al.*, 2016). Although Alt is nonessential, its absence from the prohead results in capsids of varying size, both smaller and larger than those of the wild-type phage, suggesting it has an additional, assembly-related function. Alt is also located close to, possibly on, the portal complex as supported by the fact that in giant elongated T4 heads formed by certain head mutations the copy number of Alt remains constant, at about 40 copies. This is despite increases in the copy numbers of other internal proteins (IPI, IPII, and IPIII, see below) proportional to increases in head size in these mutant particles.

T4 gp2 is a low copy (~1–2/head) DNA end protection protein that is required to block the *E. coli* exonuclease V (RecBCD); in *E. coli* lacking this nuclease phages lacking gp2 are fully infective. Both ends of the mature T4 DNA are located 80–90 Å apart and close to the portal, indicating gp2 must also be in this region and that it, like Alt, may have a secondary function, which for gp2 is likely a genome plug as mutations in it produce unstable heads that leak DNA. Genome plugs are proteins that function to prevent the packaged genome from escaping through the portal vertex until the appropriate time for DNA ejection or descent into the tail tube.

Podoviral E proteins

The short tails of podoviruses present a unique problem with regard the delivery of their genome to the cytoplasm of the host cell; they are too short to span the cell wall, compared to the tails of phages from other families. Podoviruses overcome this multi-layered barrier (consisting of inner and outer membranes, and periplasm) by having a set of E proteins, each typically present in relatively small copy number (<10), that are ejected ahead of the DNA and form a remarkable channel in the cell wall through which the genome passes, i.e., within their capsids podoviruses package an evertible tail of sorts! Structural evidence for the formation of this E-protein-derived channel has only been observed in two podoviruses to date (*E. coli* phage T7 and *Salmonella* phage P22) using cryo-electron tomography and exploiting minicells for phage adsorption to make visualization feasible.

In T7, the E proteins that form the eversible tail, are derived from a multi-protein structure, or core. That is centralized within the densely packaged DNA in the capsid (Fig. 2). The proteins that form the core are technically E proteins, due to their presence in the core and multi-functionality that this positioning affords them, they are usually referred to as core proteins. The T7 core is roughly cylindrical in shape; 265 Å high and 175 Å wide and positioned immediately above the portal complex. Although the core is not composed of large numbers of proteins, it does occupy a considerable volume in the 510 Å diameter capsid – large enough to be visualized by conventional metal staining electron microscopy.

The T7 core is not a simple cylinder, being composed of three domains, each with a different symmetry twelve-, eight-, and four-fold. The twelve-fold symmetry domain most probably represents the connector complex, whereas the other two domains are composed of three essential proteins: gps 14 (21 kDa), 15 (84 kDa) and 16 (144 kDa), present in ~10–12, 8 and 4 copies, respectively. Along the length of the core is an internal channel/cavity (diameter varies from 35 to 110 Å) that is continuous through to the outer side of the capsid due to the positioning of the core structure immediately above the portal complex. Regarding the genome, the T7 core is multi-functional, acting as a conduit via which the DNA enters the capsid (via the core inner channel). In addition, the core goes through an astonishing deconstruction, with the E proteins exiting the capsid via the portal, and then reassembling, into a channel that transverse the *E. coli* cell wall. This channel is formed by gp14, 15 and 16, with gp14 localizing in the outer membrane of the cell, and gp15 and gp16 localizing in the periplasm and cytoplasmic membrane. The packaged genome is then able to enter the cell via this channel whose development by-passes the need for specific phage or host structures employed by other phages to facilitate genome entry into the host cell (e.g., the long tail and LamB outer membrane porin required by Lambda phage). Even phages without a tail such as PhiX174 transfer their genome into a host cell by forming such an evertible tail.

Fig. 2 Cryo-electron microscopy of T7 phage. Central slices of the T7 virion (A, B and C) and orthogonal surface views of the virion (D, E and F). Cryo-Electron Tomography of the T7 virion attached to the *E. coli* cell wall shows the transformation of its inner core (A and B) into a transmembrane channel (C and F) that facilitates genome ejection into the host cytoplasm. IM, inner membrane, OM, outer membrane. Images are reproduced from EMD-1164 (A and D), EMD-5535 (B and E), and EMD-5534 (C and F). Reproduced from Agirrezabala, X., Martin-Benito, J., Caston, J.R., *et al.*, 2005. Maturation of phage T7 involves structural modification of both shell and inner core components. The EMBO Journal 24, 3820–3829. Hu, B., Margolin, W., Molineux, I.J., Liu, J., 2013. The bacteriophage T7 virion undergoes extensive structural remodeling during infection. Science 339. doi:10.1126/science.1231887.

Core structures are likely conserved features of podoviruses related to T7, such as *Prochlorococcus* phage P-SSP7, as well as more distantly related phages, such as *Salmonella* phage Epsilon15 and *E. coli* phage N4. There is considerable variation in the size and dimensions of the cores among these and other phages, likely due to variations in core proteins which function to interact with the cell walls of different bacterial hosts. However, overall it is likely most cores serve an analogous function with regard genome delivery to that of the T7 core.

Phage P22 has three essential E proteins, gp7, gp16 and gp20, that also create a channel structure that completely spans from the bottom of the baseplate through *Salmonella* cell wall, a total distance of ~40 nm! The diameter of this channel varies from ~5–10 nm, and has internal cavity of ~4–8 nm through which the DNA passes. The exact functions of the P22 E proteins are unknown, but analyzes of mutants suggest that the mature form of gp7 (gp7* which is cleaved by a *Salmonella* protease) forms the extracellular component of the channel and that the majority of the channel in the periplasm is formed by gp20. In contrast to T7, the locations of the P22 E proteins inside the head are less well defined, but the fact these proteins are ejected ahead of the DNA, and in a specific order, suggests they likely have some sort of consistent locale between particles, possibly residing close to the portal complex, and represent exciting avenues of future research (see Casjens and Molineux, 2012; Hu *et al.*, 2013; Wang *et al.*, 2019; Jin *et al.*, 2015; Agirrezabala *et al.*, 2005).

Capsids With Large Numbers of E Proteins Distributed Throughout the DNA

In contrast to the low copy number E proteins with very specific locales in the capsid, some phages have E proteins that are present in many (hundreds!) of copies with no specific structural locale, of which the capsid internal proteins (IPs) of T4 are the most well studied. There are more than one thousand molecules of three small (~8 to ~20 kDa) proteins, IPI, IPII and IPIII, and several lines of evidence support that they are dispersed throughout the packaged but highly structurally mobile 500 mg/ml DNA. These include: (1) packaged IP-nuclease fusion proteins, whether present in ~200 or ~10 copies per head, are able to cleave the genome into the same capsid-sized fragments, either quickly or slowly, suggesting they are spread throughout the DNA and are mobile within it, (2) packaged IPIII-GFP fusion proteins show gradual formation of fluorescence suggesting mobility of the fusion protein within the capsid, (3) IP proteins sediment together with the genome after both have been released after treatments that disrupt the MCP outer shell, and (4) Solid state NMR has also shown that there are specific close T4 IP-lysine-to-DNA phosphate structural contacts (see Yu and Schaefer, 2008).

T4 can form mature heads without any IP proteins as discovered by genetic analyses. Mutants with knockouts in all three IP genes showed that elimination of these three proteins resulted in only minor effects on capsid volume, and also without significantly affecting the amount of DNA packaged within the normal size capsid. These studies demonstrating the T4 IPs were dispensable were initially surprising, as their high copy numbers had led researchers to infer they had a major function. A major inference from that discovery was that the IP proteins are not essential for the stability of packaged DNA. But if the IP proteins were not required for the stability of packaged DNA, this then raised the question of what was the main function of the IPs? As it was known the T4 IPs are all injected into the host cell, this led to the hypothesis that the IPs interacted with the host in a manner that would enhance infection. It took a number of years to show that IPI binds and protects T4 DNA against a highly specific DNA modification-dependent restriction enzyme (RE), which is only present in some, mostly pathogenic, strains of *E. coli*. About 350 copies of IPI are ejected before or with the DNA, and appear to function immediately to protect the DNA they accompany in the RE containing host, since phenotypic mixing shows a functional IPI gene is not required for the RE protection. A major question still to resolve is what are the targets or functions of the other two, abundant injected proteins, IPII and IPIII.

Another *E. coli* phage with E proteins that also have an anti-restriction endonuclease inhibitor role is the myovirus P1. P1 has two large (60 and 200 kDa) E proteins, Dar A and Dar B, with four other Dar accessory proteins whose functions are also to protect the ejected genome from *E. coli* REs. These proteins enter the host through the long and narrow P1 tail and likely require refolding for the anti-RE functions to emerge. Interestingly absence of the Dar proteins shows they also play a major role in P1 capsid size determination, correlating to formation of small, middle, and normal size capsids see (Piya *et al.*, 2017; Black *et al.*, 1994; Mullaney and Black, 2014).

Capsids With Large Numbers of Co-Localized E Proteins

In recent years, increasing numbers of phages have been identified as having large masses of co-localized E proteins inside their capsids. These masses are expected to be comprised of many different proteins, of which several are present in extremely high copy numbers per capsid. To date these masses have only been identified in myoviruses with capsids with high T numbers and long >200 kb genomes, so-called “giant” or “jumbo” phages [Nb., the terms “giant” and “jumbo” have no taxonomic meaning with regard phages, and are used interchangeably by researchers. These terms were first introduced into the literature in 2002 (for “giant” phage (Mesyanzhinov *et al.*, 2002)) and 2009 (for “jumbo” phage (Hendrix, 2009)). The authors prefer “giant” as the term has historically been used to describe large phage heads, which were the product of head gene mutations in T-even and other phages, e.g., (Doermann *et al.*, 1973; Ackermann *et al.*, 1975)]. These internal protein masses occupy an appreciable fraction of the inner capsid volume, sometimes in a structure with a defined shape and volume. The first of these masses was identified as being present inside the capsid of *Pseudomonas aeruginosa* phage ϕ KZ, called the inner body (IB), in 1984 by Victor Krylov's group. It was another 25 years, and ensuing developments of high resolution CryoEM imaging and proteomics via mass spectrometry, that the structure and major components of this mass were delineated by these modern techniques (Fig. 3). The ϕ KZ IB is ~90 nm in length and 35 nm in diameter – considerably larger than that of the T7 inner core with a total volume that is greater than the total volume of some smaller capsid phages. The ϕ KZ IB has a spring- or spool-like appearance and the long 280 kb genome is spooled around it. Despite a mass of ~15–20 kDa, the exact components of the IB require clarification. Proteomic analyses of the ϕ KZ head supported the IB being comprised of numbers, possibly many, different proteins, which range in abundances. Several high abundance proteins are excellent candidates for the major IB components including gps 93, 95 and 162, all of which are paralogs and members of the Pfam12699 [Pfam is a database for protein families that for each included conserved protein contains information about that protein (e.g., function if known) and an alignment of its homologous proteins, i.e., its family]. The IB proteins are apparently ejected into the host cell based on it disappearing after phage particles adsorb to bacteria, or in particles with contracted tails and DNA-free heads. Whether the IB has an inner channel and/or is anchored to the portal complex, as in podoviral cores, are yet to be determined.

That an internal mass of E proteins is not an unusual feature may be a fairly recent discovery among “giant” or “jumbo” (genomes >200 kb) environmental phages related to ϕ KZ that infect a range of Gammaproteobacteria. The isolation of these new giant phages highlights a need for further studies on the E protein content and structure within the capsids of these phages. Data to date derived from bioinformatics, proteomic, genetic and structural analyses, support that different giant phages related to ϕ KZ, such as *Salmonella* phage SPN3US, all have large masses of co-localized E proteins. Intriguingly, despite these phages all sharing a core set of head genes, including counterparts to the abundant proteins in ϕ KZ, there is likely to be great variability in the structures and E protein content between different phages. For instance, the number of Pfam12699 paralogs in each phage varies, from two in SPN3US to seven in *Pseudomonas* phage ϕ PA3. In addition the amount of E proteins in SPN3US is estimated to be >40 MDa, approximately twice the mass of the ϕ KZ IB. Since the SPN3US genome is ~40 kb shorter than that of ϕ KZ the increase in E protein content in its capsid raises the question of whether some of the E protein mass functions to maintain the density of packaged DNA in their similarly-sized capsids.

Although the function(s) of the E proteins of ϕ KZ, SPN3US and relatives, are mostly a mystery, genetic studies of SPN3US indicate that numbers of them have essential roles. Intriguingly, several minor, essential SPN3US E proteins have predicted transmembrane domains, suggesting they may interact with one of the host membranes, possibly assisting the genome and/or other E proteins to enter the cytoplasm. Other potential functions of the E proteins include assisting with the assembly of such a large capsid, possibly regulating capsid size (i.e., analogous to the shape-determining T4 core or to a tail tape measure protein),

Fig. 3 Cryoelectron micrographs of purified ϕ KZ virions: (A) initial low-dose exposure; (B) subsequent exposure of the same field, with bubbling showing the locale of the E proteins in radiation-damaged virions. (C) Three-dimensional reconstruction of the ϕ KZ capsid viewed along the axis of fivefold symmetry that passes through the portal. The capsid has $T = 27$ icosahedral symmetry. The central axis of the inner body passes through the center of the capsid. (D) Central section of the ϕ KZ head sampled in the plane in which the inner body axis lies. (E) Multitiered structure of the inner body shown in surface rendering (left, magenta) and central gray-scale section (right). Bubblegrams reveal the inner body structure of ϕ KZ. *Science* 335, 182. doi:10.1126/science.1214120.

DNA packaging, DNA compaction in the mature head and/or roles in host takeover. The latter is supported by each of the giant phages elated to ϕ KZ and SPN3US having an essential encapsidated multi-subunit vRNAP (with diverged homology to prokaryotic RNAP β and β' , rather than the single subunit podoviral RNAPs discussed earlier) which based on studies on ϕ KZ are required for transcription of early phage genes. Interestingly, the SPN3US vRNAP is encapsidated into the DNA free prohead in an assembled form since knockout of a single one of the 5 vRNAP subunits prevents any one of this ~ 3.2 MDa enzyme from incorporation into the procapsid. Possibly, following DNA packaging by the SPN3US terminase, the vRNAP subunits are unfolded and/or disassembled, which would provide an additional function for the terminase. At very least the vRNAP subunits must be in that state by the time they exit the capsid and transverse the long, narrow SPN3US tail into the host to begin phage development. That the heads of ϕ KZ and SPN3US each have ~ 50 different proteins suggests that their E proteins collectively likely have a multitude of functions, and represent a rich resource for future studies and novel structural precedents (see Wu *et al.*, 2012; Ali *et al.*, 2017; Ceyssens *et al.*, 2014).

The Enigmas of E Proteins

Phages with yet to be identified E proteins

A major question to resolve is how many tailed phages have E proteins? It seems feasible that many phages have E proteins that are yet to be detected, or formally annotated in their genomes. This is because E protein identification is often not straightforward, requiring specialized techniques, possibly mass spectrometry, especially to identify low copy number E proteins, or Cryo-EM which is especially useful for the detection of large masses of co-localized E proteins, such as those in ϕ KZ and its relatives. Homology searches are probably the most straightforward method for inference of the presence of an E protein if there is an existing, characterized homolog in the databases, such as homologs to the core proteins of T7, or the IP proteins of T4. However, such results may be of limited use, especially for small E proteins, even ones with homologs, depending upon the extent of sequence divergence to the characterized protein.

Obviously, homology searches are of no practical use for the identification of E proteins in new phage taxa, whose genomes have a high percentage of novel genes – not an uncommon occurrence based on the overall genetic diversity of tailed phages. In such instances, there needs to be analyzes of at least one representative to assist with the inference of E protein content for related phages. As noted above, such analyzes are not insignificant, and we note that much of the existing knowledge regarding E proteins is derived from numerous and elegant studies on model phages, such as T4, T7, P22, P1, SPP1 and N4, conducted over many years. In addition, much of this knowledge is the by-product of these phages having genetic systems, which are not currently available for many phages. Despite these challenges, and based on the existing precedents, the analyzes of E proteins in novel phage types are likely to reveal many new functional classes of E proteins, possibly such as those which provide defense against prokaryotic CRISPR-Cas adaptive immune systems.

What mechanisms ensure encapsidation of E proteins?

Remarkably E proteins, in all categories discussed above, are not transferred into the procapsid after it forms, as occurs, via the portal, with the DNA. E proteins are internalized into the head at a stage when it is a protein-only prohead and only associate with the DNA after it is packaged. This knowledge is derived from characterization of the proheads in numbers of model phages, as well DNA packaging studies which have shown that proteins are excluded by the terminase from being packaged with the DNA, even proteins with high DNA binding affinities that normally bind to metabolically active cellular DNA. It can then be inferred that potentially all E proteins are incorporated into the capsid via events based on protein-protein interactions. However, it is not at all clear for many phages what the specific determinants of these, often essential, interactions are. Possibly, the mechanisms of E protein encapsidation have evolved to be as diverse as the proteins themselves.

There are several phages for which some of the determinants of E protein encapsidation are better understood, such as T4 phage (Fig. 4). In these phages their E proteins are targeted into the procapsid via attraction to proteins that are critical for prohead formation (e.g., scaffold and core proteins), and in doing so add an additional functional aspect to those proteins. The scaffold protein is typically present in hundreds of copies in the prohead – and as the name suggests – creates a structure around which the MCP shell can assemble, therefore having an important role in determining head dimensions. During head maturation the scaffold protein typically exits the capsid and by doing so creates space within the capsid for the DNA to be packaged. In phages with more complex prohead structures, such as T4, there is a main scaffold protein, gp22, and several other core proteins that are also present in many copies and work together to share the role of a single scaffold protein in other phage types. The T4 IP proteins are incorporated into DNA-free proheads based on the affinity of a short (10–19 residue), highly conserved propeptide consensus sequence found at their N-terminus (the capsid targeting sequence, or CTS) for the major essential gp22 core proteins in the procapsid.

The affinity of the T4 CTS for the core is so strong that this sequence alone can be added to foreign, non-phage proteins which results in their being packaged into the capsid. Once IP, or other targeted proteins are packaged into the core, their interaction with

Fig. 4 Maturation of the T4 head containing densely packaged dsDNA (171 kb) and E proteins (IPI, IPII, IPIII, Alt and gp2). (A) Scheme showing T4 head maturation from a protein-only spherical core to the expanded mature DNA- and E protein-containing Iprolate, mature head. (B) Transmission electron micrographs of thin-sections of *E. coli* infected with T4 showing proheads formed on the inner membrane, (C) expanding proheads moving away from the membrane after proteolysis by the prohead protease has removed scaffold protein (gp22) and E protein and major capsid protein propeptides, and (D) proheads undergoing DNA packaging to become mature heads.

the temporary scaffold protein is no longer necessary. At this point, the prohead protease, gp21, which the bulk of the evidence suggests nucleates as a kernel at the center of prohead core, is activated to resolve these CTS-scaffold interactions. The prohead protease also cleaves an *N*-terminal propeptide from the major capsid protein and all transient core proteins into small peptides, most of which exit the capsid, although a few of which are also retained within the mature capsid.

Despite their having major differences in their capsid dimensions, structures and composition to the T4 capsid, giant phages related to SPN3US and ϕ KZ likely target many of their E proteins into the procapsid via a similar mechanism to the T4 CTS system. Support for this includes that these giant phages all have diverged homologs to the T4 major capsid protein, portal, large terminase and prohead protease proteins, suggesting they share major, anciently-derived head assembly steps. In addition proteomic analyses of three phages, SPN3US, ϕ KZ, and the *Pseudomonas chlororaphis* phage 201 ϕ 2-1 identified head proteins to have had *N*-terminal propeptides removed, with cleavage in all cases being C-terminal to a glutamate residue after a short motif comparable to the cleavage substrate for the T4 protease. Proteins identified as being cleaved in all three giant phages included the major capsid protein, portal and E proteins belonging to Pfam12699. The propeptides of many highly abundant E proteins are considerably longer than the T4 CTS, i.e., 125 and 156 residues are removed from the *N*-termini of the highly abundant E proteins, gp53 in SPN3US, and gp93 in ϕ KZ, respectively. These propeptides are longer than T4 IPI (95 residues) and IPII (100 residues) proteins! *In vitro* and *in vivo* data for several of giant phage long propeptides indicate they are cleaved at additional internal cleavage motifs. This apparent redundancy in cleavage sites is likely to ensure the propeptide regions are small enough to leave the capsid, however the need for the longer propeptides in giant phage head proteins compared to those of T4 is unknown; possibly these long propeptides ensure correct localization of the E proteins in the mature head and/or act as supplements to a scaffold protein/core.

Giant phages related to SPN3US and ϕ KZ are likely to have an equivalent to the T4 CTS despite their E protein propeptides being considerably longer than those of T4. Support for this includes that the *N*-terminal 15 residues (MANFVKSKLARESVE) of the SPN3US highly abundant E protein paralogs, gp53 and gp54 are identical and contain sequences (AXE-12, SXE-15) consistent with the known cleavage motifs for SPN3US and ϕ KZ proteases. In addition, the diverged homologous abundant E protein in ϕ KZ, gp93, is processed at SLE-13, in addition to other processing sites. There are many questions yet to be resolved regarding the role(s) of the longer E protein propeptides, however it is likely there are numbers of significant variations in giant phage head assembly mechanisms relative to those of T4, which in conjunction with the functions of their novel E protein cargos represent likely sources for future novel discoveries.

In contrast to E proteins that are targeted to scaffold/core structures, some E proteins are likely targeted into the prohead via interactions with the portal complex. This interaction is based on the locales of numbers of different proteins immediately above the portal complex, such as the N4 vRNAP and T4 Alt. This location of Alt is a yet to be resolved puzzle, as Alt also has a CTS sequence like the IP proteins, albeit slightly shorter. Possibly, Alt's *N*-terminal CTS sequence processing and our recent discovery that its C-terminus is also a CTS processed propeptide removed by gp21, suggest scaffold targeting is followed by portal targeting.

Impacts of E proteins on capsid DNA packaging and ejection

The presence of E proteins raises a number of interesting questions, particularly as to how DNA packaging occurs around or through them, particularly those E proteins which are portal-localized. Do any of these proteins have any specific interactions with packaged DNA? Or conversely, do some of these proteins have limited DNA interactions so as to prevent any hindering of their ejection into the host cell, possibly ahead of the DNA? Some E proteins, such as the N4 vRNAP, Alt, and P1 Dar proteins must impact both the prohead structure and the packaging of DNA and its final structure based on the volume they would occupy in the phage head. Other proteins with specialized locations within the head potentially have less impact on the overall structure of packaged DNA as they are present in low copy number and/or have low molecular weights. However, even their presence is likely to influence the structure of the packaged DNA in specific regions, particularly near or within the portal complex, especially proteins that are bound to genome termini, such as T4 gp2.

Impacts of E proteins on DNA ejection

The successful translocation of the phage genome through the tail and into the bacterial cell is critical for infection; however, with the exception of the T7 and podoviral E protein-to-channel transformations which facilitate DNA ejection (discussed above), the impacts of E proteins on this process are poorly understood. This fundamental gap in knowledge exists in part because of the difficulty of defining these processes experimentally, which is further complicated by the number of variables in play during this process. These include the characteristics of the packaged DNA itself (length, packaged density and structure), and the structures of the tail and cell wall channel employed by the phage (whether it be bacterial or phage encoded). Notably, during the ejection process the DNA must undergo a structural transition from liquid-crystalline-like to fluid-like state, but even the speed of this transition must vary between different capsids.

Different E proteins themselves likely have different impacts on DNA ejection, simply due to dramatic variation in types, numbers, and structures within the head. For instance, the 10 kDa IPI of T4 is apparently ejected through the portal and tail tube with the DNA and without unfolding thereby promoting immediate inhibition of its nuclease target in the infected host. This does not seem feasible for other E proteins, particularly larger ones, such as the N4 vRNAP, and P1 Dar proteins, which based on their dimensions versus the internal diameters of the portal channel and tail, must undergo unfolding in the ejections process and refolding in the bacterial cytoplasm. That such permutations can occur was demonstrated by the packaging of β -galactosidase into the T4 head via an IPIII- β -galactosidase fusion and its subsequent ejection into, and activity within, the host. Physically it is not feasible that packaged β -galactosidase could exit the capsid in its folded state especially considering the structure of the myoviral

tail through which it passes. The double tube contractile tail structure (typically ~100 nm long, ~0.3 nm inner diameter) would seemingly make tail expansion to allow ejection of bulky E proteins unlikely. In addition, the appearance of the 540 kDa tetramer-dependent activity in the infected cell requires host chaperones. Hence, the ejection of the unfolded, or possibly semi-unfolded, protein must be followed by refolding and multimerization within the host. Possibly, unfolding of such non-native and native E proteins, such as β -galactosidase and Alt, that are folded and active upon synthesis prior to encapsidation, is a secondary function of the high force-generating packaging motor and the resulting DNA pressure in the full capsid. A further intriguing feature of E proteins is whether or not they resist CRISPR-Cas nuclease attack. A number of small acr proteins (anti-CRISPR proteins) comparable in size to the T4 IPs have been described that counter CRISPR-Cas attack, but thus far these proteins have been found only to be synthesized by phage origin genes in the host. Thus they are thought to function in an altruistic or cooperative fashion, unlike T4IPI that is an egoistic anti-RE protein. Could this be related to the apparent lysogeny of the acr proteins versus lytic phage proteins such as IPI. Or do E-acr's still await discovery? (see [Nussenzweig and Marraffini, 2018](#)).

Potential of E protein delivery from capsid derived nanocontainers

A related, intriguing feature of E proteins to be resolved is the mechanisms by which large proteins such as Alt, Dar, N4, giant multi-subunit phage vRNAPs, and even the 450 kDa non-phage protein β -galactosidase, are apparently unfolded within the capsid, probably while the DNA is being packaged, permitting them to be in a conformation that allows them to be ejected through the narrow portal and tail tube channels. Could this unfolding be a secondary but essential function of the high energy DNA packaging motor mechanism that, through high DNA pressure within the fully packaged capsid, promotes the ejection of unfolded or partially unfolded large proteins. Evidently these E proteins are then refolded upon ejection to display often essential enzymatic functions within the host cell? Ejection and refolding of β -galactosidase in an *E. coli* host cell argues against the necessity of special E protein structural evolution to permit transfer into a host. This high flexibility of E proteins potentially provides a means of transferring a variety of enzymes, singly or together, (e.g., Cre recombinase, CRISPR targeted Cas9, Lambda beta and exonuclease recombination proteins etc., see ([Liu et al., 2014](#))) into a host cell for gene repair or gene knockout.

Conclusions

In addition to the conserved features of all tailed phage heads – the portal, major capsid shell and DNA packaging enzyme(s) – required to form an icosahedral capsid full of densely packaged DNA, there are clearly many variations on the internal E protein composition between different phages. E proteins vary significantly in number, and locales within the head, some dispersed throughout the DNA, others form distinct structures. The reasons for these variations are in many cases still obscure but are likely linked to their functions which, based on existing precedents, potentially for most E proteins, are linked to the infection of and replication within a new bacterial host. In addition, whether fully packaged ~500 mg/ml DNA in different E protein-containing heads is spooled or folded is uncertain and could vary among these viruses.

As our knowledge of internal head or E proteins is from the phages isolated and studied to date, which represent a relatively narrow pool of total phage diversity, it is clear and exciting to consider that a myriad of internal proteins composition, structures and functions are yet to be discovered. Based on numbers of known E proteins having roles in infection and the potential of phages for biocontrol applications in a multi-drug resistant era, it could be proposed that phage E protein research is a relatively unexplored area that merits concentrated effort.

Glossary

CRISPR-Cas system Prokaryotic acquired immune system that confers resistance to foreign genetic elements and phages via degradation of recognized nucleic acid sequences.

ORFan gene Predicted open reading frame without detectable homology to coding sequences in the genomes of other organisms or viruses.

Restriction-modification system Prokaryotic innate immune system that confers resistance to foreign genetic

elements and phages via degradation of invading DNA while precluding degradation of host DNA.

Terminal redundancy Repeated genetic sequence present at both ends of a linear DNA molecule.

Triangulation number (T-number) The number of unique environments occupied by icosahedral capsid subunits; generally representative of the size and complexity of the capsid.

Introduction

Bacteriophages are the most numerous biological entities on the planet. Outnumbering their bacterial hosts by a factor of ten, there are an estimated 10^{31} phages on Earth. Ubiquitous in nature, phages are found in soil, composts, freshwater and marine environments, plants and animals, and even in the free atmosphere. With their varying lifestyles and prominent contributions to horizontal gene transfer, phages are the driving force behind bacterial populations. As such, they fundamentally influence biogeochemical cycles, the composition of microbial communities, bacterial evolution, and plant and animal health. Phages vary greatly in their morphology, virion size, genome composition and length, and have been grouped by various systems. Grouping by genome size, phages with genomes over 500 kb in length have been collectively designated ‘megaphages’ whereas phages with genomes 200–500 kb were originally referred to as ‘giant phages’ and later coined ‘jumbo phages’. Whereas all megaphages discovered to date were identified via analysis of viral metagenomic data and have not been physically isolated, an ever-growing list of jumbo phages have been isolated, characterized, and sequenced. Increased interest in jumbo phage biology has occurred hand-in-hand with a resurgence in both basic and applied phage research. These giants of the phage world offer unique insights into virus evolution, present novel genetic and molecular features, and can be especially useful in phage therapy and biocontrol applications. In this contribution we present a brief overview of jumbo phage history, discuss the challenges and methods used in the isolation and characterization of these oversized viruses and highlight a variety of unique genomic features and advanced capabilities identified in some of the 160+ jumbo phages isolated to date.

History

The story of jumbo phage biology begins, from a research standpoint, in 1968 when Gianfranco Donelli reported the isolation and initial characterization of a *Bacillus megaterium* bacteriophage named phage G. Long before the modern convenience of next generation sequencing technologies, Donelli and his colleagues recognized phage G was incredibly large, estimating the molecular weight of its double-stranded DNA (dsDNA) genome at 4.9×10^8 daltons. Phage G’s icosahedral head is 160 nm in diameter and its tail is 453 nm long. In 2011, the genome of phage G was sequenced and found to be 497,513 bp. To date, phage G holds the record for the largest isolated phage based on both virion size and genome length.

Another early discovery in jumbo phage history, the *Caulobacter crescentus* phage phiCbK was first reported by Nina Agabian-Keshishian and Lucille Shapiro in 1970. Originally characterized with head dimensions of 64 nm × 195 nm and a tail 275 nm long, phiCbK virions were more recently measured at 56 nm × 205 nm for the head and 300 nm for the tail length. The phiCbK dsDNA genome was sequenced in 2012 and found to be 215,710 bp. Due to its large head size, phiCbK helped advance the field of structural biology by serving as one of the first phages for which fine capsid structure was determined by electron microscopic image reconstruction. PhiCbK also aided in studies of the unique developmental program of *Caulobacter*, serving as a cell cycle and morphological indicator through its use of swarmer cells’ flagella and polar pili for adsorption.

The *Pseudomonas aeruginosa* phage phiKZ, originally described by Krylov and Zhazykov in 1978, is one of the most thoroughly studied jumbo phages and claims several firsts in jumbo phage history. In 2001, phiKZ became the first jumbo phage to have its

Fig. 1 GenBank jumbo phage genome submissions. Number of unique jumbo phage genome sequences submitted to GenBank each year from 2001 through 2019.

genome completely sequenced and entered in the National Center for Biotechnology Information's GenBank. PhiKZ was the first jumbo phage found to possess a proteinaceous spool-like structure, termed the inner body, inside its head and the first for which the capsid structure was resolved by cryo-electron microscopy (cryo-EM). In addition, although *Pseudomonas chlororaphis* jumbo phage 201phi2-1 was the first phage determined to form a nucleus-like compartment in infected cells, phiKZ has led the way in studies aimed at determining the assembly and function of this fascinating structure.

Changes in isolation methods and advancements in sequencing technologies have greatly eased the discovery of new jumbo phages. Thus, GenBank has seen a dramatic increase in the number of jumbo phage genomes submitted over the past few years. Whereas 0–3 new jumbo phage genomes were submitted to GenBank each year from 2001 to 2009, the past decade shows an unmistakable growth trend in submissions with a record 38 genome sequences from new and unique jumbo phages submitted in 2019 (Fig. 1). All jumbo phages isolated and characterized to date possess linear dsDNA genomes and belong to the *Myoviridae* and *Siphoviridae* families of the order *Caudovirales*. As more of these giant viruses are discovered, only time will tell whether jumbo phages exist that belong to other taxonomic families.

This is an exciting time for phage biology; the accessibility and growing abundance of genomic sequence data allows questions to be asked and comparisons to be made that were previously impossible. The growing number of new phages reported each year has also necessitated a standardization and formalization of the naming process. The history of phage biology includes multiple instances of duplicate names. For example, prior to isolation of the jumbo phage G by Donelli in 1968 a much smaller phage G was reported by James Murphy in 1957. The current naming system, proposed in 2017, aims to avoid this confusion by incorporating the common name into a longer formal name for each newly discovered virus. An example of a formal phage name using this system is vB_DsoM_JA11. This naming scheme tells us this is a virus of *Bacteria* isolated on *Dickeya solani* that belongs to the *Myoviridae* family. The last portion of the name, in this example JA11, is the unique common name given by the researcher(s) who isolated and reported the phage. In this work we have introduced phages with their formal names when available. However, most of the jumbo phages discussed herein were first reported prior to the proposal of this naming scheme and thus are referred to by their published common names. To aid the reader in further exploration of the topic, we have also indicated the host bacterium for all phages discussed.

Isolation and Characterization

Although jumbo phages represent a minority of the total collection of bacteriophages isolated in the past 100 years, they are similarly ubiquitous in nature. Jumbo phages have been successfully isolated and propagated from soil, freshwater and marine environments, sewage, and fecal samples from around the globe. The majority of jumbo phages isolated to date infect gram-negative bacteria including species from *Achromobacter*, *Acinetobacter*, *Aeromonas*, *Burkholderia*, *Caulobacter*, *Cronobacter*, *Dickeya*, *Erwinia*, *Escherichia*, *Klebsiella*, *Pectobacterium*, *Prevotella*, *Prochlorococcus*, *Pseudomonas*, *Ralstonia*, *Salicola*, *Salmonella*, *Serratia*, *Sinorhizobium*, *Synechococcus*, *Tenacibaculum*, *Vibrio*, *Xanthomonas*, and *Yersinia* (Table 1). Only six jumbo phages infecting gram-positive bacteria have been isolated, all of which infect *Bacillus* species. It is unknown whether this phenomenon simply reflects a bias in isolation efforts or if *Bacillus* species possess features unique among the gram-positive *Bacteria* that make them amenable to hosting very large phages.

The most common phage isolation technique is the double-agar overlay method in which a filtered environmental sample is mixed with a liquid bacterial culture and molten agar and then poured onto a solid agar plate. Historically, a 0.7%–0.8% molten agar solution has been used resulting in a final top agar concentration of ~0.5%. As phages infect, lyse, and diffuse through the top agar-bacteria mixture, visible plaques appear as holes in the bacterial lawn and can be picked for further propagation. With this method, diffusivity, adsorption rate and burst size can all contribute to plaque size. Thus, Philip Serwer and colleagues reasoned the great plaque count anomaly (the small number of unique phages successfully isolated relative to the large number observed by electron microscopy) could be due, at least in part, to top agar concentrations that preclude diffusion of very large phages. By using

^aHost genus but not species was provided.^bPhage listed is one of multiple phage genome sequences submitted to GenBank with >98% sequence identity.^cPhage listed is one of multiple isolates of an individual phage that have been sequenced and submitted to GenBank.

top agar concentrations as low as 0.15% they successfully isolated two new jumbo phages, *P. chlororaphis* phage 201phi2-1 and *Bacillus thuringiensis* phage 0305phi8-36, and opened the door to an era of jumbo phage discovery. The use of dilute top agar solutions, typically 0.1%–0.5%, is now widely practiced by jumbo phage biologists. For example, *Agrobacterium tumefaciens* phage Atu_ph07, which has the second largest genome of all jumbo phages sequenced to date (490 kb), was initially isolated on 0.3% top agar and later propagated on 0.15% top agar to promote the development of larger, clearer plaques. Additional modifications to standard methods also aid the isolation and propagation of jumbo phages. Double-agar plates may be incubated at a temperature lower than the host's optimal growth temperature to prevent bacterial growth from outpacing plaque formation.

Additionally, debris may be removed from environmental samples prior to plating by differential centrifugation rather than filtration to avoid inadvertent removal of very large phages.

While sequencing is the only method to precisely determine the genome length, determining the packaged DNA lengths of jumbo phages is also of interest. Packaged DNAs purified from jumbo phage virions are typically longer than the corresponding genome lengths due to genomic terminal redundancies that vary from phage to phage and can be quite extensive. Knowledge of the virion packaged DNA length, rather than the genome length, is necessary to calculate DNA packaging densities and is of interest in contemplating mechanisms of jumbo phage evolution. Pulsed-field gel electrophoresis (PFGE) is typically used to determine the packaged DNA length. By alternating the direction of the electrical field at regular time intervals, PFGE allows the resolution of DNA molecules greater than 50 kb. To avoid shearing DNA prior to electrophoresis, jumbo phage virions are concentrated, mixed with agarose to form plugs, then treated with proteinase K to digest virion proteins within the plug. The plug containing the liberated packaged DNA then serves as the sample and is loaded directly into a well of the gel. Many jumbo phage genomes are heavily modified which can cause an overestimation of the packaged DNA length. To address this issue, Jianfei Hua and colleagues developed a two-dimensional agarose gel electrophoresis (2D-AGE) protocol. Taking advantage of the fact that length does not detectably affect the mobility of very long (> 50 kb) dsDNA molecules during electrophoresis under constant voltage (nonpulsed electrophoresis), the technique involves a typical PFGE run followed by a perpendicular nonpulsed run. The first run separates DNA by length and mass/charge ratio, and the second run separates by mass/charge ratio only. The distance traveled by a phage DNA band in the second dimension relative to the distance traveled by unmodified marker bands is then used to calculate a corrected migration position predicted to occur in the first dimension if the phage DNA was not modified. In prepping jumbo phages for PFGE, it is important to note that some are sensitive to the concentrated cesium chloride solutions used in step gradients and isopycnic separations. Thus, polyethylene glycol precipitation and sucrose gradient velocity sedimentation are often used to concentrate jumbo phage solutions.

In addition to providing annotated genome sequences, packaged DNA lengths, and genomic terminal redundancy percentages, phage biologists have done an excellent job of characterizing the virion morphologies, plaque morphologies, host ranges, growth cycles, stabilities, virion protein compositions, head packaging densities, and even the transcriptional programs for many of the numerous jumbo phages isolated to date. Each of these characters aids the field in exciting comparative and evolutionary studies. In addition, novel morphological, genetic, and molecular features of several jumbo phages have been examined in greater depth and are highlighted below.

Virion Structure

Morphotypes

Bacteriophages are categorized into three orders: *Caudovirales*, *Ligamenvirales*, and Unassigned. The order *Caudovirales* represents the most numerous and widespread group of bacteriophages characterized to date. Three families belong to the *Caudovirales*: the *Myoviridae*, *Siphoviridae*, and *Podoviridae*. Members of these three families all possess unenveloped icosahedral capsids and are differentiated, morphologically, by their tail structures. Myoviruses have long contractile tails (morphotype A), siphoviruses have long noncontractile tails (morphotype B), and podoviruses have short tails (morphotype C). Each of the three morphotypes also display a range of head lengths, designated 1, 2, and 3 (Fig. 2). The vast majority of jumbo phages isolated to date belong to the *Myoviridae* family and display A1 and A2 morphologies. Exceptions include 16 different siphoviruses of *C. crescentus*, all of which belong to the genus *Phicbkvirus*. This genus of jumbo phages includes the group's namesake, phiCbK, and all members display the B3 morphotype with elongated heads and long, flexible, noncontractile tails.

Icosahedral Geometries

Jumbo phage capsids display a variety of icosahedral geometries with some possessing previously unseen triangulation numbers (T-numbers). *Sphingomonas paucimobilis* phage PAU and *E. coli* phage 121Q were the first examples of true $T = 25$ and $T = 28$ geometries, respectively, and *B. megaterium* phage G was the first example of a virus with $T = 52$ geometry. Accordingly, jumbo phages also display a fairly broad range of capsid sizes, from the 90 nm $\times$ 50 nm prolate head of *Vibrio parahaemolyticus* phage KVP40 to the 160 nm isometric head of phage G. The head structures of several jumbo phages have been determined via cryo-EM at resolutions sufficient for atomic model fitting. Interestingly, all utilize the canonical HK97 capsid fold conserved among smaller phages and simply assemble greater numbers of capsid protein subunits to generate larger heads. In addition, several different arrangements of decoration proteins have been noted among the jumbo phage capsids examined. For example, the heads of phages N3 (*Sinorhizobium meliloti*), PBS1 (*Bacillus subtilis*), G, and Bellamy (*Synechococcus* sp. WH8109) possess extra structures on their penton vertices that may help stabilize these large capsids.

Virion DNA Density

Although viruses with larger capsids are typically capable of packaging larger genomes, jumbo phage head size does not always correlate with genome length. For example, *P. aeruginosa* phage phiPA3 has a 100 nm head and a 309,208 bp genome while phage EL (also of *P. aeruginosa*) possesses a larger 140 nm head but a shorter 211,215 bp genome. The density at which DNA is packaged in phage heads is inherently important to the process of DNA injection during the initial stages of infection. Thus, jumbo phages with small genomes relative to their head sizes package additional DNA in the form of genomic terminal redundancies. Virion

Fig. 2 *Caudovirales* morphotypes. The order *Caudovirales* is comprised of the *Myoviridae*, *Siphoviridae*, and *Podoviridae* families. Jumbo phages characterized to date belong to the *Myoviridae* and *Siphoviridae* and exhibit A1, A2, and B3 morphologies. Modified from Hull, R., Brown, F., Payne, C., 1989. *Virology: A Directory and Dictionary of Animal, Bacterial and Plant Viruses*. London: The Macmillan Press Ltd., p. 165.

packaged DNA lengths, determined via PFGE or 2D-AGE, and head volumes, calculated from cryo-EM measurements, are used in estimating packaged DNA densities. Such estimates have been made for several jumbo phages and found to vary substantially, from 0.39 bp/nm³ for phage G to 0.55 bp/nm³ for phage PAU.

Differences in packaged DNA densities are likely due to variabilities in capsid structures and associated strengths. In addition, some jumbo phages possess an inner capsid structure that decreases the head volume available for packaged DNA. The heads of phiKZ and related *Pseudomonas* jumbo phages 201phi2-1, phiPA3, EL, and OBP contain a highly ordered, proteinaceous, cylindrical structure that spans the inner length of the capsid. Originally visualized by transmission electron microscopy (TEM) in 1978, the protein composition of this 'inner body' has been determined via proteolysis and mass spectrometry. The inner body is encased in DNA in virions. This poses a problem for structural studies as the inner body is indistinguishable from the surrounding DNA in conventional cryo-electron micrographs. The inner body is sensitive to radiation damage, exploding into bubbles of gaseous radiation products at electron doses that leave the surrounding capsid structure intact. Using the information from these 'bubblegrams' the structure of the inner body and its localization within phiKZ capsids was determined and used to generate three-dimensional reconstructions. The phiKZ inner body is ~24 nm wide and ~105 nm long, is tilted ~22° relative to the portal axis and is composed of multiple stacked tiers with some regions possessing six-fold symmetry. It is hypothesized to play a role in organizing the packaged genome thereby reducing internal pressure on the capsid and promoting efficient and rapid genome ejection. Interestingly, the inner body is not detected following infection indicating its constituent proteins may be injected into host cells along with the phage genome.

Head and Tail Fibers

As with small phages, jumbo phage virions frequently contain fibers. Whereas in small phages such fibers are typically found attached to the tail baseplate and/or collar, some jumbo phages display fibers in unique locations and configurations. Phage PAU virions contain a narrow, long baseplate to which several tail fibers are attached. While the baseplate fibers of many jumbo phages are fairly short (20–30 nm), those of phage PAU are longer (~65 nm). These fibers extend in various directions from the bottom of the baseplate and appear somewhat flexible in electron micrographs, giving the tail complex a string mop appearance. The tail of *Pectobacterium carotovorum* jumbo phage vB_PcaM_CBB contains several long (~120 nm) whisker-like structures. Rather than emanating from the baseplate, these whiskers cover the length of the tail sheath. Phage CBB whiskers are highly stable, remaining attached during 1.5 years of storage at 4°C, implying they serve an indispensable role.

A few jumbo phages have also been shown to possess head fibers. Phage 121Q virions contain numerous long (~100 nm), curly, hair-like structures attached to both the capsid surface and all along the sheath section of the tail. The number of these fibers varies, ranging from 0 to >20 per virion. The distal ends of the fibers appear more electron dense in TEM images, suggesting they may terminate in a globular domain. Phage 121Q head and tail fibers likely interact tightly with the host cell as it is difficult to separate virion particles from host debris during phage purification. Jumbo phage Atu_ph07 virions also contain hair-like fibers that extend from both the capsid and along the length of the tail. In TEM images, the head fibers range in length with some appearing close to 200 nm, while the tail fibers are generally shorter (~50 nm). Finally, the *Tenacibaculum maritimum* jumbo phages PTm1 and PTm5 both possess fiber-like appendages emanating from the upper regions of their heads. These fibers are 50–100 nm long and appear to function in host recognition, as follows. Electron micrographs of phage-host cell mixtures show some PTm5 virions attached to cells

via the tops of their heads, while others are attached via their tails. These head fibers are easily lost during phage purification and may serve to enhance infection in ocean currents by providing an addition initial host binding mechanism prior to tail attachment.

Genome Features

The genomes of over 160 unique jumbo phages have now been sequenced and range in length from the 204,930 bp genome of phage Bellamy to the 497,513 bp genome of phage G. Jumbo phages with the 25 largest genomes infect a range of bacterial genera including *Bacillus*, *Agrobacterium*, *Salicola*, *Escherichia*, *Xanthomonas*, *Pectobacterium*, *Cronobacter*, *Serratia*, *Yersinia*, *Salmonella*, *Klebsiella*, *Caulobacter*, and *Pseudomonas* (Table 2). Comparative genomic analyses of jumbo phage genomes have aided immensely in our understanding of these giant viruses by revealing both broader commonalities and features unique to specific groups.

Terminal Redundancies

Genomic terminal redundancies are commonly seen in the packaged DNAs of jumbo phages. Terminal redundancies in smaller phages with linear, circularly permuted genomes, such as phage T4, result from a head-full packaging mechanism in which concatemeric DNA serves as the packaging substrate. Once initiated, concatemer packaging continues until the capsid is full. Because the phage T4 head volume is larger than its genome, the packaged DNA is terminally redundant. A similar head-full packaging mechanism is thought to occur in jumbo phages which also contain linear, circularly permuted, terminally redundant genomes. Terminal redundancies, typically expressed as a percentage of the genome length, are determined by subtracting the genome length (ascertained via sequencing) from the packaged DNA length (estimated by PFGE or 2D-AGE). Whereas the terminal redundancy for phage T4 packaged DNA is 3%, the terminal redundancies for the jumbo phages PBS1, G, and PAU have been estimated at 26%, 26%, and 35%, respectively. Other jumbo phages display smaller terminal redundancies, such as 5% for phage N3, 8% for phage 121Q, and 9% for phage Bellamy. The extent of genomic terminal redundancy is largely a result of the difference in head volume and genome size. Thus, shorter terminal redundancies may be indicative of more evolved phages that have lengthened their genomes through successive acquisitions of additional unique sequences.

Genome Nucleotide Composition

Although not exclusive to jumbo phages, it is worth noting that many of the jumbo phage genomes sequenced to date possess a low GC-content, particularly in comparison to that of their bacterial hosts. The phiKZ-like jumbo phages phiKZ, 201phi2-1, and

OBP have genomic GC-contents of 36%–48%, significantly lower than the 60%–66% GC-contents of their *Pseudomonas* hosts. Likewise, the *Aeromonas salmonicida* jumbo phages 65.2, PX29, and AS5 have genomic GC-contents of 37%, 42%, and 43%, respectively, while their host's genome possesses a GC-content of 58%. Whereas phage genomes are on average 4% richer in A/T than their hosts, this difference is 15%–30% for the above-mentioned jumbo phages. Although common among sequenced jumbo phages, this contrast in phage-host GC-content is not universal and several jumbo phages have genomic GC-contents similar to those of their bacterial hosts. The higher energy cost of synthesizing GTP and CTP combined with the greater abundance of intracellular ATP and TTP may result in increased replication of virulent phages with AT-rich genomes. Thus, higher genomic AT-contents may provide phages and other intracellular pathogens an evolutionary advantage.

Nucleotide Modifications and Substitutions

Many jumbo phage genomes are heavily modified while others incorporate nucleotide substitutions. Restriction modification systems comprise a well-studied and important component of the bacterial arsenal used against infecting phages. To thwart this defense mechanism the genomes of many phages, both large and small, contain nucleotide modifications and/or substitutions that go unrecognized by restriction endonucleases.

The first identified DNA base modification, 5-hydroxymethylcytosine, was discovered in T-even bacteriophages in 1953. Since then, various modifications in which chemical groups are biologically appended to the nucleobase have been shown for all four DNA nucleotides. These chemical additions range from simple methyl groups to amino acids, polyamines, and mono- and disaccharides. Some of the host- and phage-encoded enzymes that perform nucleobase modifications utilize free nucleotides as their substrates, while others perform base modifications post-replication. Genes encoding putative DNA modification enzymes have been found in several jumbo phage genomes. Jumbo phages SPN3US (*Salmonella enterica*) and phiEaH2 (*Erwinia amylovora*) encode adenine methylase homologs, *E. amylovora* jumbo phage Y3 encodes both adenine and cytosine methylase homologs, and *Klebsiella* jumbo phage vB_KleM_RaK2 encodes two putative DNA methyltransferase homologs. Genome modification in some jumbo phages is quite extensive. For example, whereas the length of jumbo phage PAU packaged virion DNA was estimated at 690 kb via PFGE, 2D-AGE provided a calculated corrected length of 296 kb. Thus, the phage PAU genome modifications impart a charge difference great enough to result in a 26% decrease in DNA electrophoresis migration rate.

Several jumbo phages utilize nucleotide substitutions rather than nucleobase modifications. *Yersinia enterocolitica* phage phiR1-37 and the *B. subtilis* jumbo phages PBS1, PBS2, and AR9 all have genomes in which thymidine is > 99% replaced by deoxyuridine. This pyrimidine substitution is accomplished by both altering the composition of intracellular deoxynucleotide pools and protecting the newly replicated uracil-containing phage genomes from host DNA repair pathways. Because the incorporation of deoxyuridine precludes direct sequencing, these phages presented unique challenges during genome sequencing. Nuclear magnetic resonance or liquid chromatography-mass spectrometry was first employed to determine the chemical makeup of the phage genomes and was followed by different creative solutions. For phiR1-37, phage DNA was cloned using *E. coli* CJ236, a strain lacking dUTPase and uracil N-glycosylase which made partial sequencing possible. Phage AR9 was amplified using a Uracil + polymerase for library prep prior to sequencing on the Illumina MiSeq platform. As additional jumbo phages are isolated and chemically analyzed, it will be interesting to discover the novel base modifications and/or nucleotide substitutions utilized by these evolutionarily innovative viruses.

ORFan Genes

One commonality seen across the spectrum of jumbo phage genomes sequenced to date is the high proportion of predicted open reading frames (ORFs) that currently lack detectable homology in public databases. These ORFan genes encode hypothetical proteins and constitute a large percentage of many jumbo phage genomes. For example, 70%–80% of the genomes of *P. aeruginosa* phage PaBG, *Aeromonas hydrophila* phage CC2, *Acinetobacter baumannii* phage ME3, *S. enterica* phage SPN3US, and *E. amylovora* phage phiEaH2 code for hypothetical proteins. This percentage is even higher in the jumbo phages phiCbK, PBECO4 (*E. coli*), and Ea35-70 (*E. amylovora*) with 88%–89% of their genomes encoding hypothetical proteins. As an increasing number of jumbo phage genome sequences are deposited in public databases, homologs are identified and the number of ORFan genes decreases. However, the functions of the predicted proteins remain largely unknown. This is both an exciting aspect and a challenge of jumbo phage biology; it currently imparts difficulty in making functionality predictions while presenting phage biologists with thousands of new and interesting proteins to explore.

Transfer RNA Genes

In addition to the phage-host genome nucleotide composition differences noted above, virulent phages also typically encode more tRNA genes than temperate phages. Phage-encoded tRNAs tend to correspond to codons that are highly prevalent in phage ORFs and simultaneously rare in the coding sequences of their hosts. Although the inclusion of tRNA genes in their genomes is not unique to jumbo phages, the sheer number of tRNAs encoded by some of these giant viruses is nonetheless remarkable. For example, whereas phage T4 encodes eight tRNA genes, the *V. parahaemolyticus* jumbo phages KVP40 and phipp2 encode 30 tRNA genes and the *C. crescentus* jumbo phages CcrKarma, CcrMagnet, and CcrColossus encode 26, 27, and 28 tRNA genes, respectively. As with smaller phages, the tRNAs encoded by jumbo phages are thought to correspond to codons that are abundant in phage coding sequences, especially those encoding structural proteins, and serve to increase translation efficiency and virion production.

Advanced Capabilities

With the advanced functionalities encoded by their large genomes, jumbo phages and other giant viruses are beginning to blur the line between what we consider living and non-living. Many of these advanced capabilities provide a level of host independence not seen in smaller viruses while others aid virus replication by boosting intracellular nucleotide pools, countering host defense systems or precluding superinfection/secondary infections by competing phages.

RNA Polymerases

A dependence on host transcriptional machinery is a hallmark of many dsDNA viruses. Most small dsDNA phages utilize the host's RNA polymerase (RNAP) throughout infection, modulating its function via various mechanisms to ensure ordered viral gene expression. Notable exceptions include the T7-like phages and the N4-like phages. T7-like phages rely on the host RNAP immediately upon infection to transcribe the phage RNAP gene, then utilize the phage-encoded RNAP to transcribe the viral middle and late genes. In a reverse strategy, the N4-like phages inject a virion-encapsulated RNAP (vRNAP) into the host cell upon infection. The vRNAP is used to express phage early genes including a non-virion RNAP (nvRNAP) that is used to transcribe the phage middle genes. Finally, the host RNAP, modified by the phage, is used to carry out late gene transcription. Thus, even though T7-like and N4-like phages encode their own RNAPs they are still dependent on the host RNAP at particular stages of their replication cycles. Jumbo phage phiKZ and its giant relatives, however, are known to replicate completely independently of the host RNAP.

The phiKZ genome encodes multiple ORFs with homology to RNAP subunits. RNA polymerases can be divided into two families on the basis of subunit composition, conserved amino acid motifs, and three-dimensional structures. The family of single-subunit RNAPs (ssRNAPs) are known to transcribe phage, mitochondrial, and chloroplast genomes, while the family of multi-subunit RNAPs (msRNAPs) transcribe genes in cells of all three domains of life. Whereas all other known phage-encoded RNAPs belong to the ssRNAP family, phage phiKZ encodes two sets of proteins homologous to amino-(N-) and carboxy-(C-) terminal fragments of the largest msRNAP subunits. Four proteins from one set are present in phiKZ virions and likely comprise a vRNAP that is injected into host cells upon infection and functions to transcribe phage early genes. The second set of proteins is thought to comprise an nvRNAP that functions in transcription of phage middle and late genes. Similar to the nvRNAP of the N4-like phages, the phiKZ-encoded nvRNAP is found in infected cells but not virions. The phiKZ nvRNAP has been purified from infected cells and analyzed by mass-spectrometry. The enzyme is composed of five polypeptides, all products of early phage genes. Two polypeptides are homologous to N- and C-terminal portions of msRNAP β subunits, two are homologous to N- and C-terminal portions of msRNAP β' subunits, and the fifth polypeptide currently possesses no homologs in public databases other than counterparts in related phiKZ-like viruses. Curiously, the nvRNAP holoenzyme lacks similarity to σ factors utilized by bacterial msRNAPs for promoter specificity, yet specifically transcribes from late phiKZ promoters in vitro. Thus, this jumbo phage may encode a novel mechanism for RNAP promoter recognition.

To examine dependence on the host RNAP, phiKZ transcription levels were quantified at time points throughout infection of *P. aeruginosa* pre-treated with rifampicin, an antibiotic that inhibits bacterial RNAPs. Whereas bacterial transcription was decreased by the addition of rifampicin, phiKZ gene transcription was resistant to rifampicin treatment. The *B. subtilis* jumbo phages PBS2 and AR9 and the *Ralstonia solanacearum* jumbo phage phiRP31 are also resistant to rifampicin. Like phiKZ, phages AR9 and phiRP31 encode two sets of RNAP β and β' subunits. Also like phiKZ, the RNAP purified from phage PBS2-infected cells is comprised of five subunits with molecular weights roughly corresponding to those of phiKZ's nvRNAP. Because the genome of phage PBS2 has not yet been sequenced, its relationship to phiKZ is unknown at this time. Phages AR9 and phiRP31, however, are known to belong to the genus *phiKZlikevirus*. Thus, it appears multiple phiKZ-related phages have evolved a transcriptional apparatus that provides increased host independence.

DNA Repair Enzymes

Viruses are often characterized as being generally ineffective at DNA repair because they typically do not encode the extensive and complex repair mechanisms found in their hosts. Jumbo phages, however, are expanding our knowledge of virus-encoded DNA repair mechanisms. The genomes of *Cronobacter sakazakii* jumbo phage CR5, *S. enterica* jumbo phage SPN3US, and *E. amylovora* jumbo phage vB_EamM_Deimos-Minion all encode homologs of the SbcC and SbcCD nucleases involved in double-strand break repair in *E. coli* and *B. subtilis*. In addition, the genome of *E. amylovora* jumbo phage Y3 encodes homologs of RecA, UvsE, and the MmcB-like family of DNA repair proteins. RecA is well known for its role in DNA maintenance and repair, UvsE is an endonuclease involved in removing nucleotides damaged by ultraviolet radiation, and MmcB-like proteins are endonucleases thought to function in DNA repair by generating the substrates for translesion synthesis. Functional in vivo analyses of these phage-encoded proteins have not yet been performed, but jumbo phages are thought to encode and employ DNA repair mechanisms to increase the number of viable progeny virions generated during infections. The larger genome and virion sizes of jumbo phages result in fewer infectious particles assembled prior to cell lysis. For example, phage Deimos-Minion has a reported burst size of only 5 plaque-forming particles per infected bacterial cell. Therefore, jumbo phages may have evolved to encode DNA repair mechanisms to help ensure sufficient progeny production.

NAD⁺ Salvage Pathway

To boost nucleotide synthesis in their hosts, many large phages encode a nicotinamide adenine dinucleotide (NAD⁺) salvage pathway. First identified in the genome of *V. parahaemolyticus* jumbo phage KVP40, over twenty jumbo phages encode enzymes that catalyze a two-reaction NAD⁺ salvage pathway. While not exclusive to jumbo phages, the smallest phage found to encode these enzymes, *Ruegeria pomeroyi* phage DSS3phi8, still possesses a genome greater than 146 kb. The phage-encoded NAD⁺ salvage pathway, proposed by Lee and colleagues, transforms nicotinamide (NAM) into NAD⁺ via a nicotinamide mononucleoside (NMN) intermediate (Fig. 3). Genes encoding the nicotinamide phosphoribosyltransferase (NAMPTase) and nicotinamide mononucleotide adenylyltransferase (NMNATase) enzymes that catalyze the pathway are found in the genomes of several *Caulobacter* phiCbK-like jumbo phages, jumbo phages that infect *Sinorhizobium*, *Ralstonia*, *Aeromonas*, *Cronobacter*, and *Klebsiella* species, and half of the *Vibrio* jumbo phages sequenced to date. The phage KVP40 NAMPTase and NMNATase homologs were purified and found to possess the requisite activities in vitro. Transcriptional analyses showed these enzymes were expressed early in the phage infection cycle, during the metabolic phase when intracellular NAD⁺ and NADH levels are most pertinent for phage replication. Phage DNA replication rates can be greater than four times those of host DNA replication, necessitating increased deoxynucleotide production during infection. With their exceedingly large genomes, this need is even more pronounced during jumbo phage infections. It appears several of these viruses have taken this matter into their own hands, so to speak, by encoding a mechanism to provide increased levels of DNA precursors.

LPS Biosynthesis

Various temperate phages are known to encode enzymes involved in lipopolysaccharide (LPS) biosynthesis. Such enzymes are thought to function in altering the surface composition of host cells, thereby precluding superinfection/secondary infection by competing phages. Intriguingly, large clusters of genes involved in LPS biosynthesis have now been found in the genomes of two lytic jumbo cyanophages. Their genomic inclusion was originally thought to simply serve as stuffer DNA for headful packaging. However, *Synechococcus* jumbo phage S-SSM7 and *Prochlorococcus* jumbo phage P-SSM2 were isolated from geographically distant locations hundreds of miles apart in the Atlantic Ocean yet encode seven identical homologs to LPS biosynthesis genes. Thus, it is likely these LPS genes are functionally linked. Upon infection of cells undergoing suboptimal growth, some T4-like lytic phages can enter a reversible dormant state in which lytic replication is stalled following early and middle gene expression and resumes once the necessary nutrients become available. It has been suggested a similar condition, referred to as pseudolysogeny, occurs with some marine phages. If this is the case, altering the surface composition of their hosts via phage encoded LPS biosynthesis may serve to prevent secondary infections by other cyanophages, particularly smaller phages capable of faster replication, thereby ensuring production of jumbo phage progeny upon resumption of lytic replication.

Phage Nucleus

Phages and their bacterial hosts are in a continuous co evolutionary arms race in which bacteria evolve to prevent phage infection and phages evolve to counter host defense mechanisms. Bacteria encode various defense mechanisms such as DNA restriction-

Fig. 3 Jumbo phage encoded NAD⁺ salvage pathway. Nicotinamide adenine dinucleotide (NAD⁺) is synthesized from nicotinamide (NAM), phosphoribosyl pyrophosphate (PRPP), and adenosine triphosphate (ATP) in a two-step pathway catalyzed by phage encoded nicotinamide phosphoribosyltransferase (NAMPTase) and nicotinamide mononucleotide adenylyltransferase (NMNATase) enzymes. Modified from Lee, J.Y., Li, Z., Miller, E.S., 2017. Vibriophage KVP40 Encodes a Functional NAD⁺ Salvage Pathway. *Journal of Bacteriology* 199 (9), e00855.

modification systems and CRISPR-Cas systems. In addition, bacteria often evolve changes in cell surface receptors utilized by phages for attachment. Phages have countered these strategies with genome chemical modifications and/or nucleotide substitutions, anti-CRISPR proteins, and changes to virion structures used in host attachment. Jumbo phages have also been shown to utilize a unique and intriguing counter-defense mechanism coined the 'phage nucleus'. This phage encoded structure forms a proteinaceous barrier in infected cells that separates the phage genome from intracellular defense mechanisms. The compartment is centered in the cell by a bipolar spindle composed of a phage encoded tubulin-like protein. Remarkably, the proteinaceous shell of the phage nucleus allows selective entry and/or retention of specific host and phage proteins. Enzymes involved in transcription and DNA replication are enclosed within the phage nucleus, while ribosomes and metabolic enzymes are relegated to the surrounding cytoplasm. Thus, in many aspects this phage-encoded structure is indeed reminiscent of eukaryotic nuclei. During infection, phage capsids assemble on the bacterial membrane, then migrate to the phage nucleus where they dock for DNA packaging.

Although the phage nucleus was originally described in *P. chlororaphis* cells infected with phage 201phi2-1, the role of this structure as a counter-defense mechanism has been more extensively studied with the jumbo phage phiKZ. While examining anti-CRISPR capacities of *P. aeruginosa* phages, Mendoza and colleagues noticed phiKZ was resistant to a variety of CRISPR systems despite a lack of anti-CRISPR homologs in its genome. Purified phiKZ DNA was cleaved by restriction endonucleases in vitro, thus ruling out genomic chemical modifications and/or nucleotide substitutions as a counter-defense mechanism. Employing confocal microscopy to investigate the mechanism by which phiKZ resists host degradation of its genome, phage DNA was found localized to the center of infected cells, while fluorescently tagged Cas9 protein was clearly excluded from the phage nucleus. The phage nucleus also excludes host restriction enzymes, thereby protecting phage DNA from both defense mechanisms.

It is currently unclear how widespread this counter-defense mechanism is among the various jumbo phage lineages. In addition to phiKZ and 201phi2-1, a phage nucleus is also encoded by phiPA3 and public database alignment tools reveal several other jumbo phages, including vB_PaeM_PS119XW, Phabio, and KTN4, encode homologs to the phiKZ tubulin and phage nucleus shell proteins. All these phages infect *Pseudomonas* species and belong to the *PhiKZlikevirus* genus, indicating the evolutionary distribution of this counter-defense mechanism might be limited. Recently, however, a *Serratia* jumbo phage (PCH45) highly divergent from all jumbo phages sequenced to date has been shown to encode and utilize a phage nucleus structure. Thus, this counter-defense mechanism may be more widespread than previously thought. Although the phage nucleus structures assembled in phiKZ- and PCH45-infected cells protect against Type I CRISPR-Cas systems that target phage DNA, they do not protect against Type III CRISPR-Cas systems which target phage mRNAs exported to the cytoplasm for translation. Many bacteria encode both DNA- and RNA-targeting CRISPR-Cas systems and, thus, the arms race continues.

Evolution

Phages belonging to the order *Caudovirales* vary dramatically in genome lengths and head sizes, ranging from the tiny *Rhodococcus rhodochrous* phage RRH1 to the giant phage G. Across this range, two common rules apply. First, genome lengths are limited by head capacities and second, high packaged DNA densities are necessary for successful DNA injection during the initial stages of infection. As noted above, jumbo phage heads utilize the canonical phage HK97 capsid fold and simply use greater numbers of capsid protein to build larger heads. Noting this conservation at the structural level, Roger Hendrix suggested an elegantly simple 'ratchet model' of phage evolution that accommodates the common rules. In this model, mutations in the major capsid and/or scaffold proteins lead to a larger capsid with an increased T-number while packaged DNA density is maintained through head-full packaging with a concomitant increase in terminal redundancy length. The enlarged head size allows for successive incorporation of additional coding sequences into the phage genome until the genome fills the capsid. Importantly, the newly added sequences need not displace preexisting phage genes and instead simply result in a reduction in terminal redundancy length. At this point, reversion to a smaller capsid size would likely be evolutionarily disfavored as it would require deletion of genes that encode selective advantages. Thus, the larger capsid size would become locked in, as by a ratchet, and evolution could repeat the process over and over generating larger and larger phages in a stepwise manner.

The upper limit of phage size is currently unknown. Several megaphages with genomes of 540,000–735,000 bp have recently been identified during metagenomic studies. Phylogenetic analyses of their terminase genes place these behemoths in the *Myoviridae* and all are predicted to infect members of the Bacteroidetes. As methodologies are developed to isolate these megaphages, capsid analyses will reveal whether structural conservation exists across the continuum of phage head sizes. Interestingly, megaphage genomes analyzed to date possess an apparently low (<70%) coding density when annotated according to the standard genetic code. Fragmentation of predicted coding sequences indicate these phages may use an alternative genetic code in which the canonical TAG stop codon is repurposed to encode glutamine. As larger and larger phages are discovered, additional interesting and exciting evolutionary innovations will surely be revealed.

Concluding Remarks

In 2019 the World Health Organization listed the growing concern of antibiotic resistance as one of the top ten greatest threats to global health. Phage therapy, successfully developed and utilized in Eastern Europe over the past century, is experiencing a resurgence in interest among Western government agencies, health care workers, and the food industry. The typically lytic lifestyles, advanced counter-defense mechanisms, and adequately broad host ranges of many jumbo phages make them good candidates for

phage therapy and/or biocontrol applications. However, detailed knowledge of any phage therapy candidate is a crucial prerequisite to broad clinical use. There is much work to be done in characterizing jumbo phage genomes and further exploring the unique capabilities, host ranges, and infection cycles of these phages. With continuing innovations in technology and the synergistic expertise of phage enthusiasts from diverse fields, the coming decades are sure to be an inspiring and productive time for jumbo phage biology.

Glossary

Conjugation A process by which conjugative plasmids are transferred from one prokaryote to another.

Homologs A group of related proteins that share a common ancestor and likely perform similar functions.

Horizontal gene transfer The exchange of genetic material from one organism to another.

Lysogen A prokaryotic cell that harbors the genome of one or more prophages.

Natural transformation A process by which microorganisms acquire DNA from their environment.

Nuclease An enzyme that degrades nucleic acids (RNA and/or DNA).

Nucleic acid Macromolecules such as DNA or RNA which are composed of mononucleotide building blocks.

Phage A virus that specifically infects prokaryotic organisms.

Prokaryotes Single-celled organisms which lack a nucleus and belong to the domain of *bacteria* or *archaea*.

Prophage A phage genome that has been integrated into a prokaryotic chromosome.

The Phage-Host Arms Race

Phages comprise a diverse range of viruses capable of infecting specific bacterial and archaeal hosts. Independently discovered in 1915 and 1917 by Frederick Twort and Félix d'Hérelle, phages are now recognized as the most abundant entities on the planet. In fact, there are an estimated 10^{31} phage particles in the biosphere, which equates to about ten billion times more phages than there are stars in the observable universe! Phages have been found to persist ubiquitously alongside their prokaryotic hosts and outnumber them by a factor of ten to one. Phages are parasites that rely on their hosts to reproduce. Most phages replicate in one of two manners: some undergo a strictly lytic cycle, while others may choose to enter into a lysogenic cycle (Fig. 1). The former are referred to as virulent or lytic phages, while the latter are called temperate phages. Both types begin their replication cycle by attaching to a specific receptor on their host's surface and injecting their genetic material into the cell. Virulent phages strictly adhere to the lytic replication cycle, during which injection is promptly followed by the synthesis of the phage genome and proteins, and the assembly of progeny phages. These processes rely upon the host's enzymes and reservoir of chemical building blocks. Following a defined latent period, the progeny exit the cell, an event that typically leads to cell lysis and the death of the host. In contrast, following injection, temperate phages decide whether to enter into the lytic cycle or persist in a state of dormancy through the lysogenic cycle. The lysogenic cycle usually entails the integration of phage DNA into the host chromosome immediately after entry into the cell. The integrated phage is termed a prophage, and prokaryotes harboring one or more prophages are referred to as lysogens. After integration, the prophage is replicated along with the host chromosome until a stressor or other signal triggers its excision. Following excision, the prophage completes the lytic replication cycle. While these varying strategies of replication follow distinct time courses and carry differing evolutionary ramifications, it has been estimated that nearly 10^{30} such phage infections occur each day. Therefore, phages impose a substantial selective pressure upon their hosts, who must quickly respond and adapt in order to survive.

This relationship between phages and their hosts is a classic example of the Red Queen Hypothesis. Originally posited by Leigh Van Valen in 1973, the Red Queen hypothesis states that in order to maintain fitness, both the host and parasite must continually co-evolve in a veritable arms race to surmount the defenses of each party involved. Such a process can lead to the near-extinction of one side or the other; however, a series of evolutionary adaptations within host and parasite ensures that both continue to co-exist, albeit in a rather uneasy equilibrium. Accordingly, numerous studies have reported upon the various strategies phages and bacteria have acquired to ensure their continued survival. Prokaryotic defenses against phages can include passive mechanisms such as the modification of cell-surface receptors through random mutagenesis, as well as active mechanisms such as the induction of programmed cell death in the face of a phage invasion (a process known as abortive infection), or the degradation of phage-derived nucleic acids by prokaryotic immune systems. The latter can be further divided into innate immunity, such as that

Fig. 1 The lytic (left) and lysogenic (right) cycles of phage replication.

conferred by restriction-modification systems, and adaptive immunity, such as that provided by clusters of regularly-interspaced short palindromic repeat (CRISPR) sequences and CRISPR-associated (*cas*) genes.

Adaptive immune systems were once thought to be found exclusively in animals; however, the discovery of CRISPR-Cas systems proved this notion to be incorrect. These systems utilize short CRISPR RNAs (crRNAs) and Cas proteins to detect and destroy foreign nucleic acids originating from plasmids, phages and other extrachromosomal genetic elements. The general CRISPR-Cas pathway occurs in three steps (**Fig. 2**): adaptation, expression, and interference. During adaptation, short segments of invading nucleic acids (~30–40 nucleotides in length) are captured and inserted into the CRISPR locus as “spacers” in between similarly sized repeat sequences in order to record molecular “memories” of the invader. During expression, the repeats and spacers are transcribed into a long precursor crRNA (pre-crRNA). The pre-crRNA is subsequently processed (*i.e.*, chopped) within each repeat to liberate mature crRNAs that each specifies a single nucleic acid target. Mature crRNAs combine with Cas proteins to form a Cas complex (also known as an effector complex) which patrols the interior of the cell, searching for a match. During interference, foreign nucleic acids that bear sequences complementary to the crRNA (called “protospacers”) are detected and sliced by the Cas enzymes.

CRISPR-Cas systems are relatively widespread in nature – about 40% of bacteria and 90% of archaea have been found to harbor one or more of these systems. They not only protect against phage infection, but also prevent other modes of horizontal gene transfer (HGT) such as conjugation and natural transformation. Since HGT is a major driving force of prokaryotic evolution, these systems profoundly impact the microbial communities within, on, and around us. However, CRISPR-Cas systems by no means represent an impenetrable barrier as phages have been shown to evolve a variety of resistance strategies. As an example, anti-CRISPRs consist of a diverse set of phage proteins acquired in response to the selective pressures imposed by their CRISPR-Cas containing hosts. These proteins are the first-identified viral defense mechanisms that provide sustainable protection against the adaptive immunity conferred by CRISPR-Cas systems. This article will focus on the history and biology of CRISPR-Cas systems and anti-CRISPR proteins, two remarkable molecular innovations that have emerged from the perpetual phage-host arms race.

It is worthwhile mentioning that over the past decade, significant advances in our basic understanding of CRISPR-Cas pathways have enabled the development of a myriad of cutting-edge biotechnologies that continue to revolutionize genetics research and promise to offer transformative treatments for genetic diseases. Notable pioneers of CRISPR-Based technologies include Jennifer A. Doudna of the University of California at Berkeley, Emmanuelle M. Charpentier of the Max Planck Institute, Feng Zhang at the Broad Institute, and George Church at Harvard University. Such technologies include powerful genetic engineering tools that can be used to introduce precise modifications into the genomes of organisms spanning all domains of life, including humans. As a consequence, the birth of the very first CRISPR-engineered human babies was revealed in 2018 through a shocking announcement

Fig. 2 The CRISPR-Cas pathway.

that has sparked an international controversy and heated ethical debates across the globe, the conclusions of which have yet to be discerned. The topic of CRISPR-based technologies and potential applications in humans lies outside of the scope of this article. However, for more information on these topics, the reader is directed to the relevant articles referenced in the “Further Reading” section.

CRISPR-Cas, A Brief History

At the time of writing (Summer, 2019), a simple search for “CRISPR” in the NCBI (National Center for Biotechnology Information) “PubMed” database (see “Relevant Website section”) returned 13,718 publications – an immense body of literature that reflects the intense interest in the subject, yet stands seemingly at odds with its relatively brief history. The presence of the curious clusters of repeats were first observed in *Escherichia coli* in 1987, in a study lead by Atsuo Nakata at Osaka University, Japan. This study sought to characterize *iap*, a gene thought encode a proteolytic (protein-cleaving) enzyme. As almost an afterthought, it was noted that *iap* is encoded adjacent to an unusual genetic structure consisting of several 29-nucleotide direct repeats interrupted by 32-nucleotide unique sequences. In 1989, a follow-up paper by the same group was published in which these repeats were further characterized and identified in other gram-negative bacteria. Around the same time period, nearly half-way across the world, Francisco J. M. Mojica began his PhD dissertation research at the University of Alicante, Spain. While studying the gas vesicles of *Haloferax mediterranei*, a salt-loving archaeon, Mojica came across regularly-spaced repeats of 30 nucleotides separated by short stretches of unique sequences within the organism’s genome. In the years that ensued, multiple publications independently noted similar structures in diverse *bacteria* and *archaea*, including studies by Groenen *et al.* (1993), Masephol *et al.* (1996), Karlin *et al.* (1998), and Hoe *et al.* (1999). However, despite this increasing awareness of their prevalence, the biological function of these mysterious repeats remained elusive for over a decade.

Undoubtedly, early bioinformatic and computational analyses played pivotal roles in predicting their biological relevance. In 2002, the term “CRISPR” was coined to describe this special class of repeats, an acronym agreed upon by Mojica – by that time a leader of his own research group – and a team from Utrecht University lead by Ruud Jansen. Jansen’s group was the first to conduct extensive *in silico* analyses of CRISPR loci and flanking regions, and identified the conserved *cas* genes in their vicinity. However, the most important clues arose when attention shifted from the repeats and *cas* genes to the short “spacer” sequences in between them. In 2005, Mojica’s group published the first report of a systematic analysis of the spacers – it was discovered that many of them matched sequences found within extrachromosomal genetic elements such as plasmids and phages. These and other observations lead to the hypothesis that CRISPR-Cas systems provide immunity against mobile genetic elements matching the spacers through a small RNA-mediated mechanism akin to eukaryotic RNA interference. Within a few months, similar observations were reported in two additional publications from two independent research groups in France (lead by Gilles Vergnaud and Alexander Bolotin, respectively). Both reports noted that many spacers are derived from phage sequences or other extra-chromosomal elements, and Bolotin’s group also arrived at the hypothesis that CRISPR elements and associated *cas* genes likely protect cells against foreign nucleic acid invasion.

In the years that followed, several seminal studies published in quick succession by a collection of international teams revealed the basics of how CRISPR-Cas systems operate at the molecular level. One such study, published in 2007, was led by Philippe Horvath and Rodolphe Barrangou. They reported the first experimental evidence that spacers and associated *cas* genes indeed provide immunity against phages. At the time, the lead researchers were affiliated with Danisco Inc., a food production company (acquired by DuPont in 2011), and the study focused on *Streptococcus thermophilus*, a key species used in the production of yogurt

Table 1 Cas protein composition of the six CRISPR-Cas types

and cheese. Presumably stemming from an interest in developing more robust, phage-resistant bacterial strains, the team investigated the relationship between the bacterium's CRISPR-Cas locus and its phages. They demonstrated that phage infection caused the bacteria to acquire new spacer sequences that matched back to regions of the phage genome. Furthermore, by intentionally adding and removing spacer sequences from the bacterium's genome, the investigators established a positive correlation between the presence of a specific spacer sequence and resistance to the phage that harbors that sequence. One year later, a study on *E. coli*'s CRISPR-Cas system was published by John van der Oost, Stan J.J. Brouns, and co-workers at Wageningen University in the Netherlands. In this study, the investigators unambiguously demonstrated that repeats and spacers are transcribed as a long pre-crRNA, and the spacers are snipped out to produce mature crRNAs that each contain a single spacer sequence. Mature crRNAs were found to associate with a group of Cas proteins, and both components were required to interfere with phage proliferation.

As continuing insights into CRISPR-Cas mechanisms in diverse organisms appeared in the literature, clear distinctions between them began to emerge. As examples, a study published in 2008 by Luciano A. Marraffini and Erik J. Sontheimer at Northwestern University provided evidence which implied that DNA is the most likely target for CRISPR interference in the skin-dwelling bacterium *Staphylococcus epidermidis*. However, one year later, a similar CRISPR-Cas system in the archaeon *Pyrococcus furiosus* was convincingly shown to directly cut protospacer sequences within mRNA in a study lead by Michael and Rebecca Terns at the University of Georgia. Another report published in 2010 by a group at Université Laval in Quebec lead by Sylvain Moineau showed that double-stranded plasmid and phage DNA are directly cleaved within protospacer regions by the CRISPR-Cas system in *S. thermophilus*. Although these initial reports on the targets of CRISPR-Cas immunity seemed to contradict one another, further advances have reconciled these seemingly disparate observations and have led to the current understanding that there exist multiple CRISPR-Cas Types which exhibit remarkable diversity with regard to their genetic architecture, *cas* gene composition, and mechanisms of action.

CRISPR-Cas Diversity and Classification

The variety of CRISPR-Cas systems known today are believed to have evolved from a single common ancestor, which diverged over time due to its dissemination into diverse organisms and the constant selective pressure imposed by the phage-host arms race. In 2006, even before the very first experimental evidence of CRISPR-Cas function became available, Eugene V. Koonin and Kira S. Makarova of the National Institutes of Health, USA, began the process of building a framework for CRISPR-Cas classification. These investigators used computational methods to compare CRISPR loci and *cas* genes from different systems across available prokaryotic genomes in order to infer their evolutionary relationships. They also integrated their findings with structural and functional data to arrive at the current classification scheme. Therefore, it is important to note that the current scheme represents an evolving framework that is continually revisited and refined as new CRISPR-Cas systems are identified and more information about them becomes available. According to this scheme (summarized in Table 1), CRISPR-Cas systems are grouped into two broad classes and six distinct Types (I-VI). Class 1 CRISPR-Cas systems include Types I, III, and IV, while Class 2 systems include Types II, V, and VI. Each CRISPR-Cas Type is further subdivided into subtypes (indicated with a letter or alphanumeric designation). One defining feature that separates the classes is the configuration of their effector complexes: Class 1 systems all possess multi-subunit Cas complexes, while Class 2 systems possess single-subunit effectors. Furthermore, the protein composition of these complexes delineates the different CRISPR-Cas Types. All complexes contain a large Cas protein that is specific to each Type, and Class 1 complexes contain an additional small Cas protein subunit that is characteristic of each subtype. Class 1 systems are the most widespread in nature and have been found to reside in bacterial and archaeal species, while the less common Class 2 systems are found nearly exclusively in bacteria.

It now bears mentioning that the early functional insights into the general three-step CRISPR-Cas pathway emerged from studies on a diverse set of Class 1 and Class 2 systems: Type I-E (found in *E. coli*), Type II-A (found in *S. thermophilus*), and Types III-A and III-B (found in *S. epidermidis* and *P. furiosus*, respectively). Adaptation is considered the most highly-conserved

step in CRISPR-Cas immunity. Accordingly, Cas1 and Cas2, which are essential for adaptation, are found in the majority of CRISPR-Cas Types. On the other hand, the expression and interference steps of immunity, collectively referred to as CRISPR defense, are carried out by diverse Cas and sometimes even non-Cas proteins and/or additional factors. As examples to highlight this remarkable functional diversity, crRNA processing in *E. coli*'s Type I-E system is catalysed by the Cas6 nuclease, which snips the pre-crRNA within repeat sequences. In the *S. epidermidis* Type III-A system, crRNA processing occurs in multiple steps that are carried out by Cas6 and additional host-encoded nucleases. CrRNA processing is even more complicated in Type II systems. As an example, the Type II-A system in *Streptococcus pyogenes* relies upon the host-encoded nuclease RNase III as well as a second small RNA called a trans-activating crRNA (tracrRNA). The tracrRNA bears partial complementarity with the CRISPR repeats and anneals to the pre-crRNA in order to create the double-stranded RNA substrate that is required for cleavage by the host-encoded nuclease RNase III. This remarkable mechanism was first reported in 2011 in a study lead by Emmanuelle Charpentier, then at Umeå University in Sweden. The interference step of immunity is similarly diverse across all CRISPR-Cas Types and relies upon distinct sets of Cas and non-Cas proteins that degrade a variety of nucleic acid targets. For example, Type I, II and V systems recognize and cut DNA targets, Type VI systems degrade strictly RNA, and Type III systems can cut both DNA and RNA. To further illustrate their diversity, some CRISPR-Cas Types have evolved to perform functions beyond adaptive immunity, such as the regulation of endogenous gene expression. Undoubtedly, future explorations into CRISPR-Cas biology will continue to reveal such unexpected mechanisms and contribute a broader understanding of the impacts of these systems on the host organisms in which they reside.

Mechanisms of CRISPR-Cas Immunity

Given the considerable diversity across the six CRISPR-Cas Types, it is difficult to draw generalizations that would encapsulate all of their mechanistic details. Therefore, the following sections will focus on the adaptation and defense mechanisms of the best-characterized examples to serve as a starting point for a more in-depth exploration of the literature. It is worthwhile mentioning that Types I, II, and III systems have historically been the most thoroughly investigated and are considered the main CRISPR-Cas Types, whereas Types IV, V, and VI are newer additions to the CRISPR-Cas collection, and considerably less is known about their biology.

Adaptation

The first step in the CRISPR-Cas pathway, adaptation generally involves four steps: detection of foreign nucleic acids, selection of a protospacer, processing of the protospacer, and integration into the CRISPR locus as a new spacer. Since the mistaken integration of endogenous chromosomal DNA would lead to self-targeting (*i.e.*, autoimmunity) and cell death, the protein machinery catalysing these events must necessarily exhibit a strong preference for foreign nucleic acids and/or remain under tight regulation by the cell. Although adaptation is considered the most highly-conserved step of the CRISPR-Cas pathway, it remains the least well-understood. Much of the information available on adaptation has been derived from studies on Types I-F and II-A CRISPR-Cas systems.

E. coli's Type I-F system is arguably the best-characterized of the six CRISPR-Cas Types, and the first insights into its mechanism of adaptation were reported in 2012 by Udi Qimron's group at Tel Aviv University. These investigators demonstrated that Cas1 and Cas2, even in the absence of other Cas proteins, could mediate the acquisition of new spacer sequences from a plasmid. The investigators observed that new spacers are added on the promoter-proximal end of the repeat-spacer array and integration requires the presence of specific sequences in the "leader" region (*i.e.*, sequences that reside directly upstream of array). Importantly, analysis of the acquired spacers and corresponding targeted regions in the plasmid revealed the presence of conserved sequences adjacent to the protospacer (referred to as a protospacer-adjacent motif, or PAM). It is now known that PAM sequences play an essential role in preventing autoimmunity by allowing the CRISPR-Cas system to distinguish between invader-derived DNA and the spacer sequences of the endogenous CRISPR locus. Subsequent studies on this system by numerous groups, including those lead by Severinov and Semionova (2012) and Brouns (2012), revealed that there are at least two possible modes of adaptation: naïve and primed. Naïve adaptation occurs when the system encounters a brand-new phage bearing little or no resemblance to an existing spacer. This mode of adaptation depends entirely on the activities of Cas1 and Cas2, and occurs at a lower frequency. In contrast, primed adaptation occurs when the system encounters a phage that bears partial complementarity to an existing spacer. Primed adaptation is a more efficient process that relies upon the effector complex to guide Cas1 and Cas2 to the partially-matching target and facilitate further acquisition of new spacers in the vicinity. Following these initial findings, roles for host-encoded proteins in protospacer selection and new spacer integration were later described by Rotem Sorek's group at the Weizmann Institute of Science and Jennifer Doudna's group at the University of California at Berkeley, respectively, in 2015.

In subsequent studies by various groups, mechanisms of adaptation in the Type II-A system came to light. Similarly to Type I-F, adaptation by the Type II-A CRISPR-Cas system was found to rely upon Cas1 and Cas2 in addition to other Cas and non-Cas proteins encoded in the host. Although it is unclear whether this system exhibits primed adaptation, naïve adaptation in Type II-A also displays requirements for sequence motifs in the CRISPR leader region, preferences for adding new spacers to the leading end, and the presence of a PAM.

Class 1

Class 2

Fig. 3 Examples of the six CRISPR-Cas types.

Defense

Type I CRISPR-Cas systems, sometimes referred to as CRISPR-Cas3, are the most widely distributed in nature. As mentioned above, the best characterized example is the Type I-F system found in *E. coli* (Fig. 3, top panel). CrRNA expression in this system relies upon the endonuclease Cas6 (also known as CasE or Cas6e). This enzyme recognizes and cuts the pre-crRNA within each repeat. Cas6 and the mature crRNA are then joined by four additional Cas protein subunits in varying stoichiometries: one copy of Cas8 (the large Type-specific subunit, also called CasA or Cse1), six copies of Cas7 (also known as CasC), one copy of Cas5 (also called CasD), and two copies of CasB (a small subtype-specific subunit also known as Cse2). The resulting Cas complex is known as Cascade (CRISPR-associated complex for antiviral defense), a term that was coined by John van der Oost, Stan J.J. Brouns, and co-workers in 2008 in their original paper which first described this complex. Cascade can detect nucleic acid sequences that are complementary to the crRNA and positioned adjacent to a two- to six- nucleotide PAM sequence. Once such invading DNA sequences are identified, the helicase-nuclease Cas3, a protein separate from the complex, degrades the targeted DNA. An important feature of Type I systems is the requirement for perfect complementarity in the first 6–8 nucleotides adjacent to the PAM in the crRNA-protospacer match, a region known as the “seed”. Notably, the presence of a PAM and seed in Type I systems render them particularly susceptible to passive mechanisms of phage escape from immunity, whereby if a phage randomly acquires a point mutation in the PAM or seed region, it will evade CRISPR detection altogether.

Type II CRISPR-Cas systems, also known as CRISPR-Cas9 (Fig. 3, bottom panel), have historically been the most commonly used for biotechnological applications due to their relative simplicity compared to Class 1 systems. The Type II-A systems found in *Streptococcus pyogenes* and *S. thermophilus* were among the first to be functionally characterized. As mentioned earlier, crRNA processing in these systems relies upon a small tracrRNA, which bears some complementarity to the repeat-derived sequence of the

pre-crRNA. Pairing between the two RNAs facilitates crRNA processing by the host-encoded nuclease RNase III. During interference, the Cas9 nuclease bound to both RNAs recognizes and cleaves both strands of foreign double-stranded DNA matching the crRNA sequence. Similarly to Type I, Type II systems rely upon the presence of a PAM to distinguish “self” from “non-self” DNA and require perfect complementarity in a seed region to carry out interference. Accordingly, targeted phages can escape Type II immunity by simply acquiring point mutations in these critical regions.

Type III CRISPR-Cas systems are the second-most prevalent in nature and are very likely the most complex of the six Types. One of the best-characterized examples of these is the Type III-A CRISPR-Cas system found in *S. epidermidis*, also known as CRISPR-Cas10 (Fig. 3, top panel). In this system, crRNA processing relies upon the activities of Cas6 as well as host-encoded nucleases including PNPase. The mature crRNAs that result are joined by five protein subunits in varying copy numbers: one copy of Cas10 (the large Type-specific subunit, also called Csm1), one copy of Cas5 (also called Csm4), multiple copies of the Cas7 homologs Csm3 and Csm5, and multiple copies of Csm2 (the small subtype-specific subunit). The resulting effector complex is termed “Cas10-Csm”. Interference by this system has at least two requirements: First, the targeted region must be actively transcribed, and second, the crRNA must bear complementarity to the mRNA. Once the Cas10-Csm complex pairs with a targeted mRNA, it performs interference through the activities of at least three different CRISPR-associated nucleases: Cas10 cuts the targeted DNA, Csm3 cuts the targeted RNA, and Csm6, which is not a member of the complex, cuts RNA outside of the protospacer in a nonspecific (*i.e.*, sequence-independent) manner. During interference, Cas10 also releases cyclic oligoadenylates, which are small second-messenger molecules that bind to the CARF (CRISPR-associated Rossman fold) domain of Csm6 and further stimulate its nuclease activity. This remarkably sophisticated second-messenger signaling mechanism, first described in 2017 by two independent groups (lead by Virginijus Siksnys at Vilnius University and Martin Jinek at the University of Zurich, respectively) explains how Type III systems constrain the activities of Csm6 to the site of the phage infection. Interestingly, additional host-encoded nucleases are also essential for immunity through mechanisms that are still being unraveled. Unlike Types I and II systems, Type III systems do not possess PAM or seed sequences, and therefore exhibit a robust immune mechanism that cannot be easily overcome by point mutations in the phage genome. Notably, this unique feature makes Type III systems particularly suited to facilitate genome editing of lytic phages (see relevant article in “Further Reading”). However, the requirement for active transcription across the targeted region provides a route for lysogenic phages to remain unharmed by the CRISPR-Cas system provided they keep their targeted genes silent while integrating into the host chromosome.

Type IV CRISPR-Cas systems are the least well understood (Fig. 3, top panel). A recent study in 2019 by Lennart Randau and co-workers of the Max Planck Institute for Terrestrial Microbiology showed that in the Type IV CRISPR-Cas system of *Aromatoleum aromaticum*, crRNA processing is carried out by a unique Cas6 variant (Cas6v, also known as Csf5). Cas6v and the mature crRNAs are joined by three additional subunits in yet undetermined stoichiometries: Csf1 (the large Type-specific subunit), multiple copies of the Cas7 homolog Csf2, and the Cas5 homolog Csf3. The resulting ribonucleoprotein complex, termed the Type IV crRNP, has a mechanism of action that remains unknown; however, the investigators speculate that this complex functions similarly to the Type I Cascade complex.

As newer members of the Class 2 group, Types V and VI CRISPR-Cas systems have been the focal point of more recent investigations, particularly Types V-A and VI-A (Fig. 3, bottom panel). Both systems perform crRNA-mediated interference against nucleic acid invaders using single subunit effector complexes. In Type V-A systems, the large subunit is Cas12a (also known as Cpf1), while in Type VI-A systems, the large subunit is Cas13a (also known as C2c2). Both enzymes have been shown to process pre-crRNAs and cleave their targets using separate nuclease active sites. During interference, the Cas12 effector complex recognizes and cuts double-stranded DNA within the protospacer region, as well as non-target single-stranded DNA in the vicinity. In contrast, the Cas13 effector complex recognizes single-stranded RNA protospacers and subsequently degrades non-target RNA. The latter cleavage of non-target DNA or RNA upon binding a matching protospacer is termed collateral cleavage. This indiscriminate degradation of nucleic acids ensures that all invaders in the vicinity of the protospacer are shredded, and may also induce a state of dormancy in the cell due to the unintended degradation of host-derived nucleic acids. Finally, while Type V CRISPR-Cas systems have been shown to require specific PAM sequences to enable interference, Type VI CRISPR-Cas systems have a looser preference for specific nucleotides adjacent to the protospacer in a protospacer-flanking site (PFS). Thus, the latter sequence requirements may promote the facile accumulation of phage escape mutants *via* the acquisition of point mutations. It is worthwhile noting that the collateral cleavage exhibited by Types V and VI CRISPR-Cas systems has enabled the development of powerful CRISPR-based diagnostic tools. Additionally, since Type V CRISPR-Cas systems are even simpler than Type II systems with regard to their mechanisms of action, the former appear to rival the latter in their increasingly more widespread use for genome editing applications.

Anti-CRISPR Proteins

In response to the risk of encountering a CRISPR-containing host, phages have evolved a variety of countermeasures. The most common of these occurs through the passive acquisition of random mutations in the phage genome at or near the protospacer sequence. Most CRISPR-Cas systems are particularly prone to this type of escape due to presence of a seed region which is highly sensitive to mismatches, or the requirement for specific sequence motifs adjacent to it such as the PAM and PFS. Although Type III CRISPR-Cas systems do not have a seed or PAM requirement, the loss of the targeted gene in the phage constitutes a feasible mechanism of passive escape, provided the gene is dispensable for phage survival. Even though such mutations can be effective in

deterring CRISPR-Cas immunity, it is only a temporary solution since CRISPR-Cas systems can simply acquire new spacers from different parts of the phage genome to restore immunity. However, a more permanent solution to this problem lies in the diverse mechanisms of anti-CRISPR proteins.

The majority of known anti-CRISPR proteins are small, ranging in size from 50 to 150 amino acids in length. They can be found encoded in the genomes of prophages, lytic phages, or bacteria (particularly within horizontally-transferred genomic islands). Since their initial identification in 2013, reports of CRISPR inhibitors have rapidly grown to encompass over 20 distinct families targeting three of the six currently known CRISPR-Cas Types (Types I, II and V). Owing to these inhibitors' diversity in size, location, and specificity of targeting, various systematic approaches have proved necessary to elucidate each anti-CRISPR family and characterize their respective functions. The sections below highlight the seminal studies which reported the initial discoveries of anti-CRISPR proteins and the approaches that have since been applied to mine bacterial and phage genomes for these diverse CRISPR-Cas inhibitors.

Prophage-Dependent Functional Approach

Anti-CRISPRs were first reported in 2013 by a group led by Alan R. Davidson and Joseph Bondy-Denomy and co-workers at the University of Toronto, Canada. The proteins were discovered in a group of related temperate phages that infect the bacterial pathogen *Pseudomonas aeruginosa*, which contains a Type I-F CRISPR-Cas system. The authors examined a suite of 44 *P. aeruginosa* lysogens which are genetically identical with the exception of the presence of a distinct prophage within each of their genomes. Although most prophage genes are typically repressed, the authors predicted that some prophages might encode one or more genes that inhibit CRISPR-Cas function. To test for the presence of such anti-CRISPR proteins, the investigators challenged the lysogens with three CRISPR-sensitive phages that should be targeted by the bacterium's CRISPR-Cas system. As expected, the majority of the bacterial strains were able to thwart phage infection; however, a few of the prophage-containing strains failed to protect against the phages despite the presence of a functioning Type I-F CRISPR-Cas system. This suggested the lysogens harbored a prophage capable of inhibiting the CRISPR-Cas system. To identify the genetic elements responsible for this anti-CRISPR activity, the investigators compared the genomes of the CRISPR-inactivating prophages with the CRISPR-sensitive phages, and uncovered a set of five novel phage genes at a single genomic locus that were capable of inhibiting the Type I-F CRISPR-Cas system. These proteins, named AcrF1-AcrF5, constituted the very first anti-CRISPRs identified.

In a second study published in 2014, the same group identified four additional anti-CRISPRs using the same approach; however, these proteins were active against the Type I-E CRISPR-Cas system, and correspondingly were named AcrE1-AcrE4. Notably, the Type I-E inhibitors were located at the same genomic locus as the Type I-F anti-CRISPRs. The nine anti-CRISPRs identified to that date were found to exist in varying combinations across other phage genomes, suggesting that phages must acquire diverse CRISPR inhibitors to maintain their host ranges. Moreover, anti-CRISPRs were discovered outside of the prophages in genomic regions of *P. aeruginosa* that are likely mobile genetic elements, suggesting that while these proteins are subject to horizontal transfer, they are by no means restricted to transfer *via* phage.

The first insights into anti-CRISPR mechanisms were reported shortly thereafter in 2015 by members of the Davidson group. They used biochemical analyses to demonstrate that AcrF1 and AcrF2 bind directly to different protein subunits of the Type I-F effector complex and inhibit its ability to bind to the targeted DNA. In contrast, AcrF3 was unable to associate with the Cas complex and was instead shown to bind and block the function of the Cas3 nuclease-helicase. Follow-up structural analyses published in 2016 by Yongqun Zhu, Yan Zhou, and co-workers at Zhejiang University, China, showed that two copies of AcrF3 bind to each Cas3 subunit and prevent its recruitment to the Cas complex. Now, as more and more anti-CRISPR mechanisms come to light, it is becoming apparent that the majority function in two general manners: by disrupting target binding and/or inhibiting target cleavage.

Guilt-By Association Bioinformatic Approach

The lack of sequence homology between the first reported anti-CRISPRs initially hindered efforts to identify additional inhibitors through genomic comparisons alone. To bypass this challenge, April Pawluk and colleagues from the Davidson lab in 2016 considered the genomic context of the Type I-E and I-F inhibitors. They found that these anti-CRISPRs were consistently located upstream of a highly conserved anti-CRISPR associated gene, *aca1*, which encodes a predicted transcriptional regulator. Accordingly, *aca1* was used as a genomic landmark in bioinformatic screenings across phage genomes to identify diverse anti-CRISPR proteins lying adjacent to it. This method, termed a *guilt-by-association bioinformatic approach*, was used to discover two additional anti-CRISPRs acting against Type I-F systems. Furthermore, one of these was the first example of an anti-CRISPR protein capable of inhibiting two distinct CRISPR systems, Types I-E and I-F. In the same study, the team identified a second transcriptional regulator, *aca2*, adjacent to which three additional Type I-F anti-CRISPRs were identified. Subsequently, anti-CRISPR homologs were discovered across all *Proteobacteria* housing the I-F CRISPR-Cas system. Some of these proteins inhibited I-F CRISPR systems of different bacterial species despite their loosely related Cas proteins, thus underscoring the potential for anti-CRISPRs to act as broad-range inhibitors.

In a subsequent study published in 2016, a group led by Alan Davidson, Karen Maxwell, and Erik J. Sontheimer applied this guilt-by-association approach in conjunction with *aca2* to identify the first Type II CRISPR-Cas inhibitors. Originally discovered in

Neisseria meningitidis, this family of inhibitors was found to block the function of the bacterium's Type II-C CRISPR-Cas system, and thus the three inhibitors were named AcrIIC1-AcrIIC3. These findings proved significant for two reasons: First, they demonstrated that anti-CRISPRs are not limited to Type I CRISPR-Cas systems. Second, since Type II CRISPR-Cas systems are renowned for their broad genomic applications, Type II anti-CRISPR proteins have the potential to be exploited as a powerful mechanism to regulate the activities of Type II CRISPR-based technologies. Indeed, all three AcrIIC proteins discovered successfully inhibited CRISPR-Cas9 mediated genome editing within human cell lines, supporting their potential use as tools to reduce spurious cleavage events in genome editing applications. The mechanisms of action for two of the AcrIIC proteins was reported in a study led by Jennifer Doudna's group: One of these inhibitors was found to disrupt DNA binding by forcing the effector complex into a dimerized state, while the other was shown to bind and prevent Cas9 from cleaving its DNA target.

Self-Targeting Bioinformatic Approach

A distinct bioinformatics-guided method was used to identify additional anti-CRISPR genes acting against the Type II-A CRISPR-Cas system of *Listeria monocytogenes* in a 2017 study lead by Joseph Bondy-Denomy, now at the University of California in San Francisco. This methodology, termed a *self-targeting bioinformatic approach*, relies upon the prediction that the CRISPR-mediated acquisition of spacers from within a bacterium's genome would result in chromosomal cleavage by the endogenous CRISPR system and death of the cell. However, the presence of anti-CRISPR proteins within the same genome are expected to prevent such self-targeting. By identifying bacteria with self-targeting spacers, the investigators were able to discover four prophage-encoded Type II-A CRISPR-Cas inhibitors, two of which were found to block the function of the Type II-A CRISPR-Cas system of *Streptococcus pyogenes*, the very first system exploited for genome editing. The remarkable mechanism of one of these inhibitor proteins, named AcrIIA4, was elucidated in 2017 by three independent groups headed by Dinshaw Patel, Zhiwei Huang, and Jennifer Doudna, respectively. Using structural analyses, these investigators discovered that AcrIIA4 structurally mimics the PAM and binds the PAM-interacting site on Cas9, thereby blocking Cas9's ability to bind a bona fide target.

In 2018, a similar bioinformatic-guided approach was used to identify the very first Type V-A CRISPR-Cas inhibitors – these were reported in two independent studies led by Jennifer Doudna and Joseph Bondy-Denomy, respectively. Altogether, five different inhibitors were identified and experimentally confirmed to function against Type V-A interference. Notably, some of these inhibitors were shown to successfully modulate editing in human cells, again highlighting their utility for use as tools to regulate Type V-A mediated genome editing applications.

Lytic Phage Dependent Functional Approach

In 2017 and 2018, Sylvain Moineau and co-workers used a functional screen to identify additional Type II-A inhibitors within lytic phages. This approach involved engineering a Type II-A CRISPR-Cas system in *Streptococcus thermophilus* to contain spacers targeting an array of lytic phages, and then challenging the strains with each phage – those capable of reproducing within such a bacterial context were presumed to contain one or more anti-CRISPR proteins. Two such phages were identified, and further experiments in which the phages' genes were methodically tested for anti-CRISPR activity identified AcrIIA5, a broadly acting inhibitor of *S. pyogenes* and *S. thermophilus* CRISPR-Cas9 systems. Capitalizing on this successful approach, a second anti-CRISPR, AcrIIA6 was discovered despite its failure to appear concomitantly with any single *aca* gene in available phage genomes. Furthermore, homologs of AcrIIA5 or AcrIIA6 were identified in 38% of virulent *S. thermophilus* phages, indicating the prevalence of anti-CRISPRs within virulent phage genomes.

Given the widespread distribution of CRISPR inhibitors discovered within bacterial phages, it logically follows that archaeal viruses would also house anti-CRISPR genes. In fact, since 90% of sequenced *archaea* maintain CRISPR-Cas systems, it would be expected that these inhibitors might prove even more widespread amongst archaeal viruses. While anti-CRISPRs specific to archaea have yet to be thoroughly studied and characterized, a study lead by Xu Ping published in 2018 identified the first example of an anti-CRISPR protein endemic to the lytic ruidiviruses SIRV2 and SIRV3. This anti-CRISPR, AcrID1, was found to inhibit the activity of Cas10d, which is necessary for interference mediated by the Type I-D CRISPR-Cas system in *Sulfolobus islandicus*. Moreover, it was hypothesized that homologs of the newly identified archaeal anti-CRISPR are likely to be present across a diverse range of archaeal viruses as has been observed for bacterial anti-CRISPRs.

Concluding Thoughts

The microscopic war that has been raging for billions of years between prokaryotes and their viruses has given rise to an immense pool of genetic diversity, with CRISPR-Cas and anti-CRISPRs representing just two manifestations of the countless defense and counter-defense systems employed on the battlefield. Historically, the detailed investigation of such molecular weaponry has provided a fertile ground for discovery and innovation, and CRISPR-Cas research is no exception. Over the past decade, basic insights into CRISPR-Cas mechanisms have inspired the development of powerful genetic technologies, which, in turn, have propelled basic discoveries at an accelerated pace. A similar positive feedback loop is beginning to emerge for anti-CRISPR proteins, in which the continued discovery of new families and elucidation of their mechanisms are expected to not only deepen

our understanding of the evolutionary trajectories of phages and their hosts, but also impact biotechnological and biomedical fields of research. It is anticipated that in the coming years, the collection of distinct CRISPR-Cas systems will continue to expand, and anti-CRISPRs will eventually be discovered for all CRISPR-Cas Types. Beyond this, the presence of CRISPR inhibitors implies the existence of anti-CRISPR inhibitors. Though no such actors have been identified within CRISPR-containing bacterial species to date, it would not come as a surprise to see the Red Queen Hypothesis play out in this manner given such a fertile venue.

Glossary

Antibiotic resistance The ability of microorganisms to grow at high concentrations of an antibiotic.

Antibiotic susceptibility test The test to examine the microbial susceptibility to antibiotics of choice under varying concentrations of antibiotics.

Chemistry, manufacturing, and control The activities for development, manufacturing processes, quality control, and life cycle management of a drug product, to ensure the safety, efficacy, and manufacturing consistency of the product.

CRISPR/Cas CRISPR (clustered regularly interspaced short palindromic repeats) is a family of DNA sequences found in the genomes of prokaryotic organisms, originally derived from DNA fragments of bacteriophages that previously infected the prokaryote. Cas (CRISPR-associated protein) is a family of enzymes that use CRISPR sequences as a guide to recognize and cleave specific strands of DNA that are complementary to the CRISPR sequence. CRISPR and Cas together form the basis of a technology for editing genes within organisms.

Lysogenic cycle A life cycle of bacteriophages where most of the infecting bacteriophages integrate the genome into

the host genome, being passively replicated with bacterial genome as the host replicates. Some bacteriophage genomes exist as plasmids with separated replication and segregation systems, synchronizing the plasmid replication with host replication.

Lytic cycle A life cycle of bacteriophages where the infecting bacteriophage takes control of host cellular machinery to produce its own progeny and ultimately kills the host, releasing new bacteriophages to kill more hosts.

Mass spectrometry An analytical technique that measures the mass-to-charge ratio of ions from the analytes.

Molecular diagnostics An array of diagnostic techniques for analyzing the genomic and proteomic biomarkers using molecular biology tools.

Phage display A technology to study protein–protein, protein–peptide, and protein–nucleic acid interactions using bacteriophages as the vehicle to express proteins and connect proteins with the corresponding genetic information.

Phage typing A method to trace the source of outbreaks of bacterial infections by detecting single strains of bacteria with lytic bacteriophages.

Introduction

Antibiotics are one of the most important life-saving drugs for humankind. The human exposure to antibiotics has been dated back to 350–550 Common Era, where trace amounts of tetracycline have been found in human skeletal remains, likely due to the consumption of tetracycline-containing food. Traditional Chinese medicine practiced at least 1000 years ago was also found to have antibiotic activities. The modern “antibiotic era” started with the discovery of penicillin by Alexander Fleming in 1928 and, 15 years later, the mass production and introduction to the public for treating bacterial infections. In the next decades from 1950s to 1970s, the discovery and development of novel antibiotics flourished and revolutionized medicine by reducing global morbidity and mortality.

The bacterial resistance to antibiotics was reported shortly after their discovery and became prevalent after the massive introduction. The resistance to penicillin became widespread 24 years after the commercialization, whereas the resistance to methicillin was identified in the same year as its introduction (Fig. 1). Most of the resistance is attributed to proteins expressed in bacteria, which inactivate antibiotics via different mechanisms including efflux pumping and enzymatic cleavage. The misuse and overuse of antibiotics further accelerate the resistance by creating a selective pressure to kill the susceptible bacterial strains and allow the resistant strains to thrive. This resistance became a problem after the 1980s as bacteria more rapidly developed resistance to new antibiotics and a dramatic slow-down on the development of new antibiotics with only three new classes of antibiotics marketed after 2000 (Fig. 1).

Over the last decade, Antibiotic Resistant (AR) bacteria are recognized as global threats and projected to cause more annual global deaths than cancer by 2050. Each year in the US, more than 2.8 million people are infected with AR bacteria, causing at least 35,000 people to die directly from the infection. The annual nationwide cost to treat hospitalized patients with AR bacterial infections is estimated between \$30 and \$50 billion (between 2012 and 2015). These infections, if not diagnosed early and treated with effective drugs, can lead to severe diseases like sepsis which has a high mortality.

Current standard diagnostic method for bacterial infections is to amplify bacterial pathogens from culture (i.e., bacterial culture), followed by the species identification with biochemical tests or *mass spectrometry* analysis. Upon identifying the pathogens, a separate *Antibiotic Susceptibility Test* (AST) is used to select effective treatments with the total testing time of two to five days from sampling to obtaining AST results. Patients with acute infections (e.g., bloodstream infection) cannot afford such a prolonged testing time, thus physicians have no choice but to empirically treat these patients with broad-spectrum antibiotics before the test results would be available, which accelerates the resistance to last-resort drugs. Several *molecular diagnostics* emerged for rapid bacterial identification;

Fig. 1 Timeline of antibiotic introduction and the identification of antibiotic-resistant bacteria from 1940 to 2015. Data modified from Center for Disease and Control and Prevention (<https://www.cdc.gov/drugresistance/about.html>).

however, all of them still require a preliminary bacterial culture, a process that takes at least 8–12 h to amplify culturable bacteria. It is almost impossible to detect bacteria that are difficult to culture or are unculturable. Therefore, we need to develop a rapid and accurate diagnostic tool and combine with evidence-based treatments to combat AR bacteria.

In the past decade, bacteriophages (Phages) have gained attention from scientific community as an alternative therapy for AR bacterial infections. Phages are viruses that infect bacteria with two different life styles, *lytic* and *lysogenic* cycles. In the lytic cycle, the infecting phage takes control of host cellular machinery to produce its own progeny and ultimately lyse (i.e., kill) the host bacteria, releasing new phages to kill more bacteria. In the lysogenic cycle, most of the infecting phages become a *prophage* by integrating the genome into the host bacterial genome, being passively replicated with bacterial genome as the host replicates. If a bacterium with a prophage is under environmental stresses (e.g., UV), the prophage may be excised from the host genome and enter the lytic cycle, a process called induction.

Phages hold great potential to be a new tool for detecting and treating AR bacterial infections because of two major advantages: *specificity* and *self-replication*. However, there are at least two major limitations: *narrow host range* and *resistance of the bacteria to phages*. Many excellent reviews describing the medical application of phage have been published in the last 10 years. The goal of this article is to discuss the history of phage development as therapeutic and diagnostic tools, to dissect the major advantages and limitations of phage technology associated with therapeutic and diagnostic applications.

The Development of Phage as Therapeutics for Bacterial Infections

Phages were independently discovered by two microbiologists: Frederik Twort in 1915 and Félix d'Hérelle in 1917, and named "bacteriophage" after the idea of "bacteria-eater." Shortly after d'Hérelle's discovery of *Shigella* phages, he acknowledged the potential of using phages to treat bacterial infections (i.e., phage therapy) and successfully applied lytic phages to treat *Salmonella gallinarum* infected chickens. This success led to the first human clinical trial in 1921, where five patients with bacillary dysentery were treated with *Shigella* phages and recovered. In 1927, additional clinical trials were conducted in India for treating cholera with phages, which showed an over 50% decrease in mortality compared to the control groups.

After the initial success of clinical trials, more scientists began to test phage therapy for other bacterial infections. The outcome of these tests, however, was mixed success and raised criticisms on the study design and the quality of phage products. The enthusiasm of phage therapy waned after the discovery and mass production of penicillin gained popularity in 1940s, shifting the pharmaceutical focus to finding and developing novel antibiotics as the treatment for bacterial infections. Research on phage instead moved towards the fundamental understanding of phage biology with several phages (e.g., λ , T4, and M13) became powerful model systems for studying gene regulation, protein engineering, restriction modification, and among others, transforming the knowledge learned from phages into modern biology disciplines including molecular biology and genetics.

This shift of focus continues to bring the technologies developed from phages at the center of modern drug development, including the introduction of "phage display" technology in 1985, which created bestselling protein therapeutics and the more recent discovery of "CRISPR/Cas system" which holds a great potential to be the next generation precision therapy by its targeted genome editing capability. Despite the success from phage-derived technologies, phage therapy has received mixed interests around the globe. From the 1940s to 1990s, Western countries largely abandoned the idea of phage therapy, whereas the former USSR still extensively exploited its capability through the 1970s. Today, phage therapy is still available as a treatment option for AR bacterial infections in the Republic of Georgia.

A notable phage therapy center in the Republic of Georgia, Eliava Institute, has developed several phage products for treating septic, topical, and intestinal bacterial infections. Despite these products were subjected to clinical trials and are commercially available in Eastern Europe, they are not approved elsewhere, because the standards of clinical trials and pharmaceutical manufacturing procedures in the former USSR and the Republic of Georgia do not comply with international regulations. With the emergence of multi-drug resistant bacterial strains and the slowed development of new antibiotics, Western countries have a renewed interest in phage therapy.

Fig. 2 Interests of phage therapy indicated by the number of review article from 1991 to 2019 (data extracted from PubMed).

Table 1 Overview of randomized and placebo-controlled clinical trials for phage therapy

Industry sponsor	Indication	Target bacterial species	Phase	Study number	Year	Product	Number of phages in the product	Evaluated patient population	References
Intralytix	Venous leg ulcers	<i>Pseudomonas aeruginosa</i> , <i>Staphylococcus aureus</i> , <i>Escherichia coli</i>	I	WIRB, protocol# 20061649	2007–2008	WPP – 201	8	39	Rhoads <i>et al.</i> (2009)
Biocontrol Limited	Chronic otitis	<i>Pseudomonas aeruginosa</i>	I/II	2004–001691–39	2009	T4-like coliphages	6	24	Wright <i>et al.</i> (2009)
Nestle	Pediatric diarrhea	<i>Escherichia coli</i>	I	NCT00937274	2016	Biophage-PA	11	115	Sarker <i>et al.</i> (2016)
Pherecydes Pharma SA	Burn wounds	<i>Pseudomonas aeruginosa</i>	I/II	2014–000714–65	2018	PP1131	12	25	Jault <i>et al.</i> (2019)

This interest gradually grew as indicated by the steady increase of published review articles discussing phage therapy in Western scientific journals (Fig. 2). Additionally, four randomized, placebo-controlled Phase I/II clinical trials were conducted to address one of the biggest criticisms on phage therapy – suboptimal design of clinical trials (Table 1). All four trials pointed towards promising safety; however, three failed to demonstrate the superiority of phage treatment compared to controls or standard of care. In contrast, several case studies of compassionate treatments showed positive outcomes. Phages appear to have a niche in treating some bacterial infections but still have many unsolved questions from the fundamental mechanisms of action to the manufacturing and regulatory pathway. More high quality data is needed to turn phage therapy into the reality.

The Development of Phage as Diagnostics for Bacterial Infections

Current diagnostic tools for bacterial infections primarily rely on bacterial culture combined with (1) secondary biochemical tests or mass spectrometry analysis to identify the pathogen species or (2) molecular diagnostics to detect species-specific and bacterial virulence genes. Both methods require at least 8–12 h to amplify the pathogens and a separate AST for selecting treatments. An ideal diagnostic tool should only detect viable bacteria, identify species, and provide treatment recommendations from a single test. If test results were available in one to three hours, physicians could initiate evidence-based treatments and minimize the empirical use of broad spectrum antibiotics.

Phages have been used to detect bacteria since the development of *phage typing* in 1950s, where bacterial strains can be typed (i.e., classified) by the plaques created from a panel of lytic phages on the bacterial lawn. This technique is still used in some hospitals to monitor the bacterial outbreaks by detecting clusters of virulent strains. A reporter phage was later developed to detect *Mycobacterium tuberculosis*, a slow growing bacterial species, by incorporating a luciferase gene into the phage genome. After phage infection, the luciferase is expressed in minutes with the activity to be detected by the addition of luciferin, dramatically reduced the diagnostic time from weeks to one day. Importantly, this reporter phage is compatible with AST, allowing the selection of effective antibiotic treatments and the screen of new anti-tuberculosis drugs.

With a better understanding of phage genomics and structure, the engineering effort turned to the use of phage capsids to display functional molecules on the surface of phage virions, enabling the detection of phage-infected bacteria either through conjugated fluorophores or direct fluorescent signal from the displayed molecules (Table 2). Despite extensive research on

Table 2 Summary of modern diagnostic phages

Technology	Target bacteria	Diagnostic phage	Signal detection	Limit of detection	Detection time	Compatible with AST	References
Luciferase	<i>Mycobacterium tuberculosis</i>	TM4	Luminescence	500–5000 cells	<24 h	Yes	Jacobs Jr. <i>et al.</i> (1993)

Note: NA, not available.

diagnostic phages, very few products of this type have moved into clinical testing or become commercially available, owing to some practical challenges associated with phages. Below we discuss the major advantages and limitations of phage technology.

Major Advantages of Phage Technology

Specificity

Although broader host range phages do exist, more commonly a phage species is typically limited to infecting one bacterial species or even to several lineages within a species. This specificity is driven by *phage adsorption*, a process generally consisting of three steps, initial contact, reversible binding, and irreversible attachment to the target bacteria. The last step is mediated by a *specific* interaction between the often bacterial species-specific surface receptor and the receptor binding protein on the phage virion, allowing the accurate detection of target bacteria for diagnostic phages and the minimum impact on commensal bacteria for therapeutic phages.

Self-Replication

Lytic phages replicate inside the target bacteria, kill the bacterial host, and release dozens to hundreds of progenies, continuing the bacterial killing. This self-replicating nature allows the sustained release of therapeutic phages from the target bacteria, potentially reducing the dosing amount and frequency. As the phages only replicate in *live* bacteria, this process enables the detection of live pathogens when infected with diagnostic phages.

Major Limitations of Phage Technology

Narrow Host Range

A phage's host range is defined as the spectrum of bacteria that it infects. Some phages have a narrow host range and only infect few strains in a bacterial species, limiting their ability to treat or diagnose infections caused by single or multiple bacterial species. While this limitation has been overcome with the use of multiple phage species to expand the range of host targets, new challenges emerge for therapeutic applications, as discussed later in this article.

Phage Resistance

Bacteria and phages co-exist in an evolutionary arm race, where a bacterial species may already have or will inevitably develop resistance against selected phages. The pre-existing phage resistance will increase the false negative results from diagnostic applications and decrease efficacy in therapeutic applications, while the acquired phage resistance may be difficult to monitor and control in human for therapeutic phages.

Additional Challenges for Phage Therapy

Preclinical Data Translation

Translating results from preclinical models to human is a significant and common challenge for drug development. Early studies showed that the outcome of in vitro phage experiments did not always give the same results as in vivo studies. Additionally, the

in vivo efficacy from one study may not be consistent with another study or translatable to the efficacy in humans. This is largely due to the poor study design and the discrepancies in biology between species. High quality preclinical data from in vitro and representative in vivo models is essential for the approval of phage therapy.

Safety and Efficacy

Phages are generally considered to be safe to human because no major adverse events were reported from previous clinical trials. In animal models, circulating phages are also shown to be rapidly removed by liver and spleen in the absence of target bacteria. Recent studies suggested that, while phages can enter human cells via at least three mechanisms, phagocytosis, transcytosis, and receptor-mediated endocytosis, the entered phage virions were degraded in one day without damaging the viability of cells. However, it is not clear how phages interact with human immune cells. Such interaction may trigger immunogenicity with specific responses against therapeutic phages, leading to the development of anti-phage antibodies. The clinical impact of these antibodies ranges from no apparent effect, to the reduced efficacy of phages by neutralizing and/or eliminating phages from the body, to the safety concern from the induced allergic responses. To ensure the safety and efficacy of phage therapy, more studies are needed to understand the potential immunogenicity triggered by phages.

Dosing Strategies

To maximize the therapeutic activity of phage, several dosing strategies should be considered, *dose determination*, *dose interval*, and *route of administration*, to improve the common pharmacology effects, (1) Pharmacokinetics: the fate of phages after being administered to humans, and (2) Pharmacodynamics: the impact of administered phages on humans. These pharmacology effects are more complex for phage therapy compared to antibiotics or protein therapeutics because of the population (from self-replicating nature of phages) and evolutionary dynamics between phages and bacteria. Several population dynamic models were developed to predict the short-term dynamics (i.e., days) for in vitro phage-bacteria interactions; however, it is still challenging to model these interactions in humans in a clinically relevant time frame (i.e., weeks to months). Additionally, most of the models were developed for systems with a single phage and a single bacterial species, there is limited understanding on systems with multiple phage (i.e., phage cocktail) and bacterial species.

A unique aspect to consider for phage therapy is the *dosage form*: single phage versus phage cocktail. Phage cocktails were developed to expand the host range and overcome phage resistance from bacterial mutants. While the cocktail sometimes outperforms the single phage treatment, it remains difficult to determine the mechanisms of action and the associated synergy (if any) from the cocktail. In-depth understanding of population and evolutionary dynamics among cocktail phages and the target bacteria may facilitate a more rational design of phage cocktails and prevent phage resistance.

The rise of bacterial phage resistance in human clinical trials has been shown to be alleviated by subsequent treatments with different phages selected as able to propagate on the phage-resistant bacteria. This selection process typically continues until the patient showed no symptoms, making the entire dosing process “personal”, as the next dosing regimen depends on the bacteria evolved in a given patient. The major advantage of this process is the use of target phages. However, the selection process is time-consuming and labor intensive with several manufacturing and regulatory challenges, as discussed below.

Chemistry, Manufacturing, and Controls (CMC)

CMC are the activities for the development, the manufacturing processes, the quality control, and the life cycle management of a drug product, to ensure the safety, efficacy, and manufacturing consistency. Several CMC challenges were identified for phage therapy. (1) High levels of bacterial endotoxin in the drug product and loss of infectivity during the shelf-life storage were reported in phages used in recent clinical trials, raising the concerns of product quality. (2) Phage therapy has been evaluated as the personalized treatment process (i.e., personalized phage products over the course of treatment) or as the single off-the-shelf product (i.e., fixed composition of phages in a single drug product). The off-the-shelf products have a clear CMC pathway that is likely to be similar to biologics; however, bacteria will eventually develop phage resistance. On the other hand, the personalized treatments may be more effective in reducing phage resistance; however, there is no clear general strategy to control the product quality and establish shelf-life in a timely manner for each treatment cycle.

Regulatory Pathway

There is no approved phage therapy in Western countries; therefore, the regulatory pathway is not clear. To engage with phage therapy developers, the US Food and Drug Administration and National Institutes of Health hosted workshops to discuss current drug approval processes and other considerations for phage therapy (e.g., phage therapy workshop, Rockville MD, 2017). Experts from both agencies also participated in public phage conferences to share their perspective on phage therapy (e.g., phage congress, DC, 2019). The message from these agencies suggested that, in general, the regulatory pathway will be similar to biologics, and there is a need for more high quality preclinical and clinical data to demonstrate the safety, efficacy, and manufacturing consistency of therapeutic phages.

Environmental Impact

As shown in the antibiotic industry, the mass production (> 100,000 tons per year) causes overwhelming pollution in the environment and accelerates antibiotic resistance. Mass production of phages will inevitably create a similar level (if not worse) of environmental impact from the toxic byproduct during manufacturing to the evolutionary pressure on natural bacterial populations. If phage therapy becomes widely available for treating bacterial infections, it will be essential to have proper regulation of phage production and surveillance programs dedicated to monitor the environmental impact and avoid the unintended consequences from antibiotic industry.

Additional Challenges for Phage Diagnostics

Phage Manipulation

To improve sensitivity, modern diagnostic phages were developed by the genetic manipulation of phage genome, which requires a delicate selection of the target location on the phage genome for editing and the discovery of new functional molecules to improve the sensitivity. Poor engineering strategy will result in damaged phages with little infectivity compared to the wild type phages.

Multiplex Testing

Many bacterial infections are caused by different species; therefore, the ability to test multiple bacterial species (i.e., multiplex testing) becomes critical for improving the diagnostic efficiency and reducing the sample requirement. Current diagnostic phages were designed to target single bacterial species with single channel of detection on the functional molecules. With limited functional molecules (e.g., fluorophores) available for engineering, it is challenging to apply diagnostic phages for multiplex testing.

Intracellular Bacteria

Several bacterial pathogens replicate inside human cells and transport between neighboring cells, which are often difficult to identify unless they outbreak and cause symptoms. Moller-Olsen and co-workers recently showed that K1F phage can enter human epithelial cells and kill the intracellular *E. coli*. It is not clear if this reaction is universal for different human cells, phages, and bacterial species. More studies at clinically relevant conditions are needed to understand the potential of using diagnostic phages to detect intracellular bacteria.

Sample Interference

Sample interference is a common issue of traditional bacterial culture and modern molecular diagnostics, where the interference may come from contaminating bacteria picked up during sample collection or from the sample matrix, impacting the test sensitivity, specificity and predictive values. Some interference may be partially mitigated by repeated tests; however, not all patients (e.g., neonate) can afford the samples for re-testing. Again, future work should address the performance of diagnostic phages in clinically relevant conditions and compare the assay performance to current standard techniques.

Market Acceptance

Bacterial culture has been utilized for several decades as the gold standard for bacterial diagnosis; therefore, customers may be reluctant to switch to other methods. Current diagnostic phages rely on the luminescence detection or the fluorescent imaging analysis; both are low throughput and labor intensive. To compete with bacterial culture, the diagnostic phages should be developed as a high throughput assay with a minimum labor requirement and compatible with current diagnostic workflow in the hospitals and clinical testing laboratories.

Conclusions

Interest in using phages to fight AR bacterial infections remains high. As noted above, the emergence of AR bacteria and the shortage of new antibiotic development prompt the search for alternatives. Phages are approved as prophylactic agents for bacterial contamination in food products in the US and several other countries; therefore, they have the potential to be the alternative diagnostics and therapeutics for bacterial infections. The emergence of successful phage treatments of patients who were otherwise untreatable with antibiotics has gained attention from the media and ignited passion to pave the regulatory approval path for phage therapy.

However, challenges remain at every level of development. For the single phage product, bacterial phage resistance is inevitable. It is not clear how fast bacteria will develop such a resistance and the impact of phage resistance on bacterial virulence. Will

co-evolutionary arm race between phages and bacteria exacerbate bacterial virulence or reduce bacterial fitness? For phage cocktails, the mechanism of bacterial killing is not clear as the individual and synergistic efficacy is difficult to dissect. An important question remains: how to rationally design the treatment with a single phage product, a phage cocktail, or a combination of phage(s) with antibiotics? We also have limited knowledge of human immune responses to phages and similarly the interaction between human cells and phages. Will phages transduce virulent genes from a virulent bacterial host to non-virulent bacteria or even human cells? The limited data available makes it challenging to define the clinical safety and efficacy profile for phage therapy.

While there is tremendous body of work in biochemistry, structural, and genetic aspects of phages, the data is more concentrated on selected model systems. Every phage species is unique with its own properties and should be treated as an individual entity in the product. To produce a single phage product or a phage cocktail, one must monitor the quality attributes of every phage species during the manufacturing processes and the shelf-life. How to define the shelf-life and control the quality of phages are critical CMC issues for phage therapy and depend on the dosage form (cocktail versus single phage product) and the treatment process (off-the-shelf versus personalized). Finally, there is an urgent need for high quality studies to evaluate the clinical efficacy with *sufficient patient population* and the performance of diagnostic phages in *clinically relevant conditions*, which is at present hard to come by. Once these challenges are solved, phages can be considered as the alternative tools to fight AR bacterial infections.

Bacteriophage Vaccines

Introduction

Vaccines are one of the most effective medical interventions in the human history. More than 60 vaccines against 26 pathogens are currently available in the US market. Most of these are whole-pathogen vaccines (CDC data updated on April 13, 2018, for website link see “Relevant Website section”). Historically, vaccines were developed using mainly the whole pathogen, either the attenuated (live-attenuated vaccines) or the inactivated (heat- or formalin-killed vaccines) organism. However, whole-pathogen vaccines generally pose significant safety risks including reversion to a pathogenic form, severe reactions in immunocompromised hosts, and adverse effects such as allergic responses. Therefore, the focus in recent years has shifted to the development of recombinant subunit vaccines, which contain only the well-defined antigenic molecules of the pathogens, which are a much safer alternative to the whole-pathogen vaccines.

Virus-like particles (VLPs) represent one of most promising approaches to design subunit vaccines. VLPs are nanometer scale particles with precise dimensions that are assembled with viral structural proteins. However, they generally lack the viral genome and hence, non-pathogenic. Due to their favorable characteristics as seen in viral pathogens such as size, geometry, highly ordered and repeat structure, they can, by simulating a viral infection, stimulate robust immune responses by the host immune system. Successful VLP vaccines have been developed and commercialized worldwide such as hepatitis B vaccine and human papillomavirus vaccine.

It would be extremely useful if there is a “universal” platform that could assemble any antigen, or antigens, and generate VLP vaccines against one or multiple pathogens. Bacteriophages (phages) are highly promising candidates to develop such a platform because of their size, surface structure, stability, safety, biodegradability, and low cost of manufacture. Here, we describe some unique features of phage T4 that make it an effective VLP vaccine platform, both in terms of design and effectiveness.

Architecture of Phage T4

The phage T4 belongs to *Myoviridae* family and infects the *E. coli* bacterium. Thus, it is innocuous to humans. Phage T4 consists of three major components; head (capsid), tail, and tail fibers. These are assembled by independent pathways and joined together to form the infectious virion. The application of T4 phage as a VLP platform mainly involves the head, which is an elongated icosahedron, 120 nm long and 86 nm wide (Fig. 1). It is built with 930 copies of the major capsid protein gp23* (“*” represents the cleaved form) (48.7 kDa), which form the hexagonal capsid lattice. Eleven of the twelve vertices are occupied by pentamers of the vertex protein gp24* (55 copies per capsid) (46 kDa). The twelfth vertex is a unique vertex where the dodecameric portal protein (61 kDa) resides. A central channel in the dodecamer serves as a portal for entry of DNA during genome encapsidation and for exit of genome during infection. The dodecameric vertex is where the packaging motor docks for DNA packaging and later, neck and tail attach after packaging is terminated and motor dissociated. A unique feature of the T4 head is that it contains two non-essential outer capsid proteins; 870 copies of the small outer capsid protein (Soc, 9.1 kDa) and 155 copies of the highly antigenic outer capsid protein (Hoc, 39 kDa) (Fig. 1). Soc monomers assemble into trimers at the quasi three-fold axes and clamp the adjacent gp23* hexameric capsomers, thus reinforcing an already very stable capsid structure and protect the pressurized capsid against harsh extracellular environment (e.g., pH 11). Hoc is a linear “fiber” containing a string of four domains. It binds at the center of each capsomer as a monomer through its COOH-terminal domain whereas the NH₂-terminus is projected at ~170 Å distance away from the capsid. Hoc might facilitate attachment of phage to bacteria.

Phage T4 as a Vaccine Platform

Although Soc and Hoc provide survival advantages to the virus in the natural environment, they are completely dispensable under laboratory conditions. Deletion of these genes has no significant effect on phage assembly, productivity, or infectivity. Moreover, purified Soc or Hoc proteins bind to Hoc⁺Soc⁺ capsid with high specificity and nanomolar affinity, properties that are not greatly compromised by attachment of an antigen at the NH₂- and/or COOH-termini. Actually, the NH₂- and COOH-termini of Soc and the NH₂-terminus of Hoc are well exposed on the capsid structure, thus allowing efficient display of foreign proteins fused to Soc and Hoc on the capsid surface. Proteins as large as ~83 kDa anthrax protective antigen (PA) or 129 kDa β -galactosidase were efficiently displayed. However, the COOH-terminal domain of Hoc has the capsid binding site and is not desirable for antigen display. The T4 antigen display can be accomplished either *in vivo* or *in vitro*.

Fig. 1 Structural model of bacteriophage T4. Three major components of phage T4 – Head, tail, and tail fibers – are indicated. The enlarged capsomer (inset) shows the major capsid protein gp23* (930 copies; * represents the cleaved form), Soc (blue, 870 copies), and Hoc (orange, 155 copies). Yellow subunits at the five-fold vertices correspond to gp24*. The unique portal vertex (gp20) connects the head to the tail.

Fig. 2 Schematic of phage T4 *in vivo* VLP display system. A. The Soc- or Hoc-antigen fusion gene is cloned into a donor plasmid flanked by homologous arms. B. The recombinant T4 phage is generated by homologous recombination between wild-type (WT) T4 and donor plasmid upon infection of *E. coli*. C. The fusion proteins are expressed under the control of a T4 promoter and assembled on T4 capsids during the propagation of the recombinant T4 phages.

In Vivo VLP Assembly

For *in vivo* VLP assembly, the antigen gene is inserted into T4 genome at the NH₂- or COOH-termini of Soc or the NH₂-terminus of Hoc by homologous recombination between T4 phage genome and a donor plasmid, which contains an antigen gene flanked by two homologous arms of T4 genome (Fig. 2). The recombinant T4 phage containing the antigen-Soc or -Hoc fusion gene is then selected and amplified. Upon infection of *E. coli*, the fusion proteins are expressed under the control of a T4 promoter and

Fig. 3 Schematic of phage T4 *in vitro* VLP display system. The polyhistidine-tagged Soc-fused antigen is purified from *E. coli* and assembled on purified Hoc⁺Soc⁺ T4 phage by mixing the two to generate the VLPs. The same principle is used for the display of Hoc-fused antigens or targeting molecules.

assembled on the capsid *in vivo*. The resulting phage is purified and used as a VLP vaccine. The advantage of *in vivo* assembly is that, once the recombinant phage is constructed, the VLP vaccines can be produced by a simple procedure at the scale needed. However, the copy number of the antigen on the VLP could vary greatly because different Soc or Hoc fusion proteins may be expressed to different extents and the Soc/Hoc binding sites don't have to be completely occupied. Additionally, it would be difficult to assemble multiple antigens to generate multivalent vaccines.

In Vitro VLP Assembly

For *in vitro* VLP assembly (Fig. 3), Soc- or Hoc-antigen fusion proteins are expressed in *E. coli* under the control of a strong promoter such as the phage T7 promoter. The proteins are then purified and displayed on phage by mixing the recombinant protein with the purified Hoc⁺Soc⁺ T4 phage. The Soc- or Hoc-fusion proteins can also be expressed using a mammalian expression system for antigens requiring specific post-translational modifications. This approach has many advantages. First, functional characterization of the purified Soc- or Hoc-fusion proteins can be performed prior to display to insure the production of full-length antigens and their native-like function(s). Second, the composition of the *in vitro* assembly mixture can be adjusted to generate multivalent vaccines against one or more pathogens and to control the copy number (Fig. 3). For example, by adding two different anthrax antigens fused to Soc, LFn-Soc, and Soc-PA4 to the reaction mixture, T4 phage nanoparticles simultaneously displaying both the antigens could be generated. The copy number of each antigen was proportional to the ratio of antigen molecules to binding sites added to the assembly mixture. Third, *in vitro* assembly allows building of oligomeric complexes through interaction with a displayed antigen. The tripartite anthrax toxin complexes containing LFn, PA, and EF could be assembled using the Soc-fused LFn molecules anchored on the capsid. Finally, *in vitro* assembly allows display of antigens that require post-translational modifications such as glycosylation for function by simply producing the antigens using a mammalian expression system.

T4 capsid nanoparticle has several features that make it a desirable platform to design VLP vaccines. The availability of up to 1025 Soc and Hoc binding sites per capsid provide a great deal of flexibility to generate symmetrically arrayed antigens on a nanoparticle at high density. Such ordered and repetitive patterns of display on phage capsid mimic the patterns exhibited by pathogenic viruses and are considered to be important for activation of the innate immune systems. Another useful feature of the T4 VLP is that the interior of the capsid can also be used for DNA vaccine design. This can be accomplished either by filling an empty capsid *in vitro* using the DNA packaging motor with DNAs that can express vaccine antigens upon delivery into human cells or by inserting DNAs into phage genome by CRISPR engineering. Furthermore, the T4 nanoparticles can be targeted to antigen presenting cells such as the dendritic cells by displaying specific ligands such as anti-DEC205 monoclonal antibodies on the capsid. The NH₂-terminus of the Hoc fibers projected 170 Å away from the capsid wall provide a unique opportunity to display molecules with considerable reach to capture the cell surface receptors present on the targeted cells.

Phage T4 VLP Vaccines

T4 nanoparticle platform has been used to develop VLP vaccines against a number of pathogenic bacteria and viruses, such as *Bacillus anthracis*, *Yersinia pestis*, HIV-1, foot-and-mouth disease virus (FMDV), classical swine fever virus (CSFV), and bursal disease virus. Here, we focus on our recent work on the design of biodefense vaccines against *B. anthracis* and *Y. pestis* using the T4 *in vitro*

VLP display system. *B. anthracis* is the causative agent of anthrax, a deadly disease that leads to rapid death upon exposure. It is listed as a tier 1 biothreat agent by the United States Center for Disease Control (CDC). *Y. pestis* is the causative agent of plague also known as Black Death, which is one of the deadliest infectious diseases known to mankind. Currently, there are no Food and Drug Administration (FDA)-approved plague vaccines for mass vaccination in humans. Although there is a licensed anthrax vaccine consisting of a filtered crude culture supernatant of *B. anthracis* strain V770-NP1-R adsorbed to Alum adjuvant, it is limited to military and high-risk health care workers due to its significant reactogenicity in vaccinated individuals. Therefore, a safe and effective subunit vaccine has been a high priority to protect the public against these biothreats.

The anthrax protective antigen (PA) is a primary target for the development of subunit vaccines. To develop an anthrax VLP vaccine, PA fused to the NH₂-terminus of Hoc was displayed on T4 capsid by *in vitro* assembly to the maximum copy number of ~155 molecules per capsid. When intramuscularly injected into mice with no adjuvant, the anthrax VLP vaccine elicited 6.5-fold higher PA-specific IgG when compared to those immunized with soluble PA adjuvanted with Alhydrogel. Similarly, PA could be fused to Soc and assembled on T4 capsid. In a rhesus macaque model, T4 phage displayed with both PA-Hoc and PA-Soc, after three intramuscular injections, again with no adjuvant, induced up to ~500 µg/ml of PA-specific IgG and provided 100% protection against aerosol challenge with lethal *B. anthracis* Ames strain spores (85 LD₅₀). No side effects due to T4 VLP vaccination were observed in either animal model.

Two *Y. pestis* virulence factors, the capsular protein (Caf1 or F1) and the low calcium response V antigen (LcrV or V) are the main targets for plague vaccine design. We engineered a F1 mutant that produces a monomer as opposed to heterogeneous aggregate in the case of the native F1 and fused it to V to generate a bivalent F1mutV antigen. To develop a plague VLP vaccine using T4 platform, the F1mutV was fused to the NH₂-terminus of Soc and assembled on T4 capsid by *in vitro* display up to about 660 copies per capsid. Without any adjuvant, the plague T4 VLP vaccine when immunized in mice or brown Norway rats (natural host for *Y. pestis*) elicited very high titers of F1V-specific antibodies, higher than the soluble antigen adjuvanted with Alhydrogel. Of particular note is that the T4 VLP vaccine also induced IgG2a and IgG1 antibodies whereas the soluble F1mutV vaccine mainly elicited IgG1 antibodies. IgG2a represent T_H1 immune responses whereas IgG1 reflects the T_H2 responses. This and additional data indicated that the T4 VLP vaccines induced more balanced T_H1 and T_H2 immune responses unlike the traditional subunit vaccines. Stimulation of both arms of the immune system, humoral (T_H2) and cellular (T_H1), is considered to be beneficial for protection, in particular for clearance of intracellular pathogens. Indeed, the T4 VLP vaccine provided 100% protection in both the mouse and brown Norway rat models against intranasal challenge with the most lethal *Y. pestis* CO92 strain up to as high ~5000 LD₅₀ dose.

Taking one step further, we combined both the anthrax and plague T4 VLP vaccines into one and tested its efficacy in mouse, brown Norway rat, and New Zealand white rabbit models. With two intramuscular injections at three week intervals, the robust immunogenicity observed with single vaccine was recapitulated in this bivalent anthrax-plague vaccine and no antigen competition was observed. Most importantly, the vaccine conferred 100% protection against dual challenges with 1 LD₁₀₀ of anthrax lethal toxin and 200–400 LD₅₀ of *Y. pestis* CO92. Protection was observed whether the challenges were administered in sequence or simultaneously, in both mouse and brown Norway rat models. The vaccine also provided 100% protection in rabbits against 200 LD₅₀ challenge with lethal *B. anthracis* Ames strain spores. Thus, the phage bivalent vaccine could protect against two deadly biothreat agents, inhalational anthrax and pneumonic plague.

Other Phage Vaccine Platforms

Other phages have also been used as scaffolds for development of VLP vaccines (Fig. 4). In fact, the abundance and diversity of phages provides many choices for designing VLP vaccine according to specific purposes. For example, the size of VLP was reported to be an important factor for eliciting immune responses. The size of T4-VLP described above is about 120 × 86 nm. Most other phage capsids are smaller. The commonly used phages include λ, T7, MS2, and Qβ, which have sizes of 60 nm, 56 nm, 26 nm, and 28 nm respectively. The capsid of λ phage is composed of the major capsid protein gpE and the outer capsid protein gpD. The gpD, which has a copy number of 405–420 molecules per capsid stabilizes the capsid against the internal pressure of the packaged phage genome (48.5 kb). Therefore, it is an essential protein for the WT phage but dispensable for phages with shorter genomes. The COOH-terminus of gpD has been extensively used for display of epitope peptides. However, it is possible to display larger antigens but at reduced copy number. Although both *in vitro* and *in vivo* display have been used to assemble the foreign peptides fused to gpD, *in vivo* display is the preferred method because phages or capsids produced in the absence of gpD are less stable for *in vitro* display.

The capsid of T7 phage is assembled with the major capsid protein gp10. However, a small portion of gp10 undergoes a –1 frame-shift at the COOH-terminus of gp10 (345 amino acids) to produce a slightly longer gp10 (398 amino acids). The former is named gp10A and the latter, gp10B. The gp10B is not essential for capsid assembly and, therefore, has been used for display of peptide epitopes and antigens as fusions to the COOH-terminus of gp10. Although the copy number is generally limited, as high as 415 copies of about 50 amino acid antigen peptides have been displayed on the T7 phage by *in vivo* display.

Two small single stranded RNA phages MS2 and Qβ have also been used for VLP vaccine design. The capsid of these phages is composed of 180 copies of major coat protein (CP) to which a peptide epitope can be fused and self-assembled both *in vivo* and *in vitro*. However, successful capsid assembly requires WT CP, hence the copy number of the epitope-fused CP is limited. Phage Qβ also contains three to five copies of A1 protein, which is a large 196-amino acid extension at the COOH-terminus of CP as a result

Phage	Capsid size (nanometer)	Phage protein(s) used for display (copies/capsid)	Preferred molecule for <i>in vivo</i> display	Main display scheme	Maximum copy number	Display of mammalian expressed antigen
T4	120 X 86	Hec (155) Sec (870)	Full length protein, Peptide	<i>in vivo</i> <i>in vitro</i>	1,025	Yes (<i>in vitro</i>)
A	60	gpD (405-420)	Peptide	<i>in vivo</i> <i>in vitro</i>	420	Possible (<i>in vitro</i>)
T7	56	gp108 (415)	Peptide	<i>in vivo</i>	415	No
MS2	25	CP (180)	Peptide	<i>in vivo</i>	180	No
Q β	28	A1 (3-5) or its mutant (96)	Peptide	<i>in vivo</i>	86	No

Fig. 4 Properties of various phage display systems.

of infrequent read-through at the termination codon. This feature has been used as a way to display peptides through fusion to the COOH-terminus of A1.

Filamentous phages such as M13 and fd have also been used for vaccine development, although these phages have been most powerful for display of random peptide libraries. The 900 nm long phage fd filament is composed of about 2700 copies of major coat protein pVIII. At one end of the filament are 5 copies each of minor capsid proteins pIII and pVI, while the other end contains 5 copies each of minor capsid protein pVII and pIX. The pVIII can only display short 6–8 amino acid peptides, while the minor capsid proteins can display proteins although at low copy number, 1–5 molecules per filament.

Many vaccine candidates have been developed using different phage VLP platforms described above. Readers are encouraged to read the review articles list below for details of these vaccine candidates.

Conclusion Statement

Vaccine development thus far has been individualized for each disease. Consequently, it takes enormous time, resources, testing, and manufacturing hurdles, in order to bring a vaccine into human use. The question remains if a “universal” VLP platform can be developed to design vaccines against many infectious diseases. Phages in general, and T4 phage in particular, provide the necessary architectures for such a platform. Phages are highly stable, can be manufactured relatively easily and cost-effectively, is considered to be safe, and has no significant pre-existing immunity in humans. The features of phage T4; large size, high antigen capacity, robust immunogenicity without adjuvant, ability to co-deliver DNAs and targeting molecules, and ease of engineering using CRISPR provide distinct advantages to manipulate this VLP platform and design efficacious vaccines against pathogens, including complex and emerging pathogens such as HIV and Flu. The phage platforms could therefore potentially streamline and accelerate the whole vaccine development process in the future.

Acknowledgments

This research has been supported by grants from the National Institute of Allergy and Infectious Diseases (current: AI111538 and AI081726) and in part from the National Science Foundation, to VBR. We thank many current and past post-doctoral fellows and graduate students who contributed to bacteriophage T4 vaccine research, in particular Jennifer Jiang, Laura Abu-Shilbayeh, Zhihong Zhang, Qin Li, Sathish Shivachandra, Taheri Sathaliyawala, and Guofen Guo, and Wadad Alsalmi; collaborators Drs. Glossary

Genome mosaicism Phage genomes that have patches of similar sequence and patches of quite different sequence are considered to “mosaically related”. Such patches are said to be “mosaic sections” and are thought to have arisen by horizontal exchange among divergent phages rather than by differential divergence.

Host range The hosts that can be successfully infected by a given phage.

Metagemone A collection of all the nucleic acid sequences present in an environmental sample.

Phage cluster A set of related phages with nucleotide sequence similarity that spans > 50% of their genomes as determined by nucleotide dot plot.

Phageome Collection of sequences identified as bacteriophage-derived in an environmental or metagenomic source.

Plaque assay An assay for phage infection that relies on mixing the bacteria and phage prior to plating, and observing the plaques that arise on plate.

Prophage A phage genome whose lytic genes are not expressed and which replicates in concert with the host genome, either as a plasmid or integrated into the host chromosome.

Protein cluster A cluster of protein sequences derived from adjacent genes in a sequencing contig in metagenomic studies.

Virion The stable virus particle that is released from infected cells and is capable of binding to and infecting other sensitive cells.

Virome Collection of sequences identified as virial due to the extraction method and derived from an environmental or metagemone source.

Introduction

The diversity of the functional, physical and genetic aspects of bacteriophages (or phages), viruses that infect bacteria, seemingly knows no bounds. This is an exciting time of new discovery in this field, and with each new study known phage diversity continues to expand. Phages have been found that infect nearly every bacterial species that has been examined, and since they replicate rapidly and kill host bacteria, they are important players in the ecology of bacteria and thus the overall ecology of Earth. Bacteria, and thus their phage predators, are critically important in such varied processes as global nitrogen and carbon cycling, animal and plant diseases of many types and the human immune response. Although a few phages have been very successfully studied since the 1940s as model systems for the understanding of basic molecular biology of life, their amazingly high abundance was only fully recognized when particles with their unique tailed phage-like morphology were quantified in environmental samples in the 1980s and 90s. These studies showed that there are 10^{31} – 10^{32} tailed phage virions on Earth, which probably corresponds to a global ratio of about ten for each bacterial cell. In addition, the advent of facile nucleotide sequencing of bacterial genomes showed that most harbor one or more quiescent phage genomes called prophages. Other phage types beyond the tailed phages may be less common, but their virions are more difficult to recognize in environmental samples and so their abundance is less well understood.

Phages exist that have several different general behavioral types. (1) Lytic phages always replicate to make progeny virions and kill their host upon infection. (2) Temperate phages can, depending on the conditions at the time of infection, either replicate lytically to make progeny or turn off their lytic, cell killing genes and replicate as a prophage in synchrony with the host chromosome, either integrated into the host chromosome or as a plasmid. (3) Filamentous phages continuously replicate progeny and they escape the cell without overtly killing it. Temperate prophages often express “lysogenic conversion” genes that give the host cell some advantage, and in response to environmental signals many prophages can undergo “induction” to enter the lytic cycle to produce progeny and kill the host cell.

Like all viruses, phages are extremely diverse, and they exist as eight very different general types that include virions that carry ssDNA, dsDNA, ssRNA or dsRNA chromosomes and that have several different morphologies (Table 1). Virion chromosomes can be linear or circular in different phage types. The genome sizes of known phages range from less than 4 to nearly 500 kbp, and the number of encoded proteins varies commensurately. Most phage virions contain one nucleic acid molecule, but the dsRNA phages contain several separate chromosomes. (See the International Committee on Taxonomy of Viruses [ICTV] world-wide-web page: website link provided in “Relevant Websites section” for detailed descriptions of the various types.) In addition, the five different protein folds of the protein that makes up the virion’s protective coat suggests that this critical aspect of phages has been “invented” at least five times during the course of life on Earth, and divergence within these groups indicates that they are all very ancient. The chromosomes of different nucleic acids and the > 100-fold variation in genome size means that there are a multitude of varied molecular strategies for phage replication and survival in nature that cannot all be described in this venue.

Table 1 Eight types of bacteriophages

Group	Well studied members	Virion DNA	Member lifestyles	Virion type
dsDNA				
<i>Caudovirales</i> (tailed phages)				
<i>Myoviridae</i>	T4, P2	Linear, 28–500 kbp	Lytic or temperate	Icosahedral ^a head, long contractile tail
<i>Siphoviridae</i>	λ , SPP1	Linear, 36–125 kbp	Lytic or temperate	Icosahedral ^a head, long non-contractile tail
<i>Podoviridae</i>	T7, P22	Linear ^b , 16–90 kbp	Lytic or temperate	Icosahedral ^a head, short tail
<i>Corticoviridae</i>	PM2 ^c	Circular, 10–11 kbp	lytic (or temperate?) ^d	Icosahedral, internal lipid membrane
<i>Plasmaviridae</i>	AVL2 ^c	Circular, 12 kbp	lytic	Pleomorphic. external membrane
<i>Tectiviridae</i>	PRD1	Linear ^b , 15–18 kbp	Lytic or temperate	Icosahedral, internal lipid membrane
ssDNA				
<i>Inoviridae</i>	M13, f1	Circular, plus strand, 4–9 kb	Lytic or temperate	Filamentous/helical
<i>Microviridae</i>	ϕ X-174	Circular, plus strand, 4–6 kb	Lytic (or temperate?) ^e	Icosahedral
dsRNA				
<i>Cystoviridae</i>	ϕ 6 ^c	Linear, 3 molecules, 13 kbp	Lytic	Icosahedral, external membrane envelope
ssRNA				
<i>Leviviridae</i>	MS2, Q β	Linear, plus strand, 3–5 kb	Lytic ^f	Icosahedral

^aSome species have elongated pseudo-icosahedral heads.

^bA protein is covalently attached to 5'-ends in all *Tectiviridae* and some for *Podoviridae*.

^cOnly a small number of isolates have been studied.

^dThe studied members of this group appear to be lytic, but PM2-like sequences (possible prophages?) are present in the genomes of some bacteria.

^eRecent reports of *Microviridae* genomes embedded in bacterial genomes have led to the suggestion that some may be temperate.

^fA poorly understood carrier state has been reported for phage LeviOr01.

In spite of their staggeringly high abundance and the different kinds of virion structures, the true diversity of phages was not appreciated until genome sequencing became easy to perform. Phages MS2 (ssRNA), ϕ X-174 (ssDNA) and λ (dsDNA) were the first virus genomes to be sequenced with high cost and great effort in the late 1970s and early 1980s, but as sequencing costs and required effort declined over the past several decades the number of phage genome sequences in the public databases has increased dramatically. Indeed, up to 100 phage genomes can now be sequenced in a single Illumina type run for only about ten US dollars per genome, and there are currently (in 2019) over ten thousand available genome sequences for “authentic” phages (defined as phages that have been propagated in the laboratory and not including prophage sequences in bacterial genomes or phage sequences assembled from metagenomic information). As phage genome sequences were compared to one another it was quickly realized that genetic differences are very much greater than easily observable virion morphology differences, and the latter are insufficient to distinguish phages into informative groups of similar individuals. For example, *Siphoviridae* tailed *Escherichia coli* phages λ (Accession No. JQ086376) and *Bacillus subtilis* phage SPP1 (Accession No. NC_004166) virions appear very similar by negative stain electron microscopy, but they have essentially no recognizably similar nucleotide sequence. Thus, the study of the diversity of phages is necessarily the study of the diversity of their genome sequences.

There are eight general phage types (Table 1), and where more than a few individual phages are known, there is substantial sequence diversity among individuals, but only in the *Caudovirales* or tailed phages is this diversity known to extend to very major differences in gene content. The other seven types appear at present to have limited ranges of gene content, for example in the two other best studied types the *Microviridae* have about ten genes that include largely homologous but not identical virion assembly and replication gene complements and variable lysis and other accessory genes, and the *Leviviridae* have four genes that include conserved virion assembly and replication genes and variable lysis genes. Large numbers of authentic phage genome sequences are known for only the tailed phages, so we will focus on the tailed phages in the remainder of this review.

Understanding the Nature of Tailed Phage Diversity and Phage Classification

The tailed phages have been historically separated into three types, the *Podoviridae* that have short tails, *Siphoviridae* that have long non-contractile tails and *Myoviridae* that have long contractile tails. These tail differences, which easily seen by electron microscopy of virions, reflect different strategies for DNA delivery into cells but do not correlate with other features of phage lifestyle details. The tailed phage classification method that is most similar to cellular ribosomal RNA based classification relies on the fact that there are (only) three proteins for which homologs are encoded by all tailed phages, the major capsid protein (MCP, which forms the head shell), portal protein (channel through which DNA is packaged and ejected) and the large terminase subunit (DNA packaging motor protein), but such an approach that uses one or a few proteins can be confused by the extensive horizontal exchange of genetic material that has characterized phage history. In addition, phages and thus these proteins, especially MCP and large terminase, are so diverse that they can have little to no easily recognizable sequence similarity, making comparisons of distantly related phages difficult. Thus, comparison of such a small set of genes, although usually informative, can incorrectly identify overall group membership, but more importantly it does not show important differences within groups of related phages

(discussed in more detail below). More informative methods for overall phage classification utilize whole genome or proteome approaches. Among these are nucleotide dot plot analysis, Average Nucleotide Identity (ANI; nucleotide sequence identity between two genomes), and whole proteome similarity determinations (such a proteomic tree that compares all the encoded proteins or proteome conservation that measured the fraction of genes that are homologs).

Each of these strategies has weaknesses and strengths. A strength of whole genome nucleotide analysis is that it doesn't depend on correct annotation of genes or encoded protein function. An advantage of the proteome-based approaches is that proteins often retain recognizable homology after the encoding nucleotide sequences have diverged beyond the point of having recognizable similarity, so more distant protein relationships among phages can be detected and analyzed. Protein comparison methods are also particularly useful in the analysis of metagenomic data where proteins encoded by genes or gene clusters, rather than whole genomes, are usually compared. A significant disadvantage of whole genome nucleotide or proteome sequence clustering or tree construction, is that such approaches average differences and similarities across the genomes, losing important information on the variable relationships within genomes.

Whole genome nucleotide dot plots on the other hand are capable of showing varied relationships across highly mosaic and rearranged genomes. This operational approach was pioneered by Graham Hatfull and colleagues for easy visualization of relationships within large sets of phages by overall genome similarity in a way that does not disguise differential relationships across the genomes (genome mosaicism, see below). Groups of highly related phages recognized by the method are defined as "clusters" of phages that have dot plot diagonal line similarity that covers $\geq 50\%$ of their genomes, which generally correlates with $> 50\%$ ANI and $> 40\%$ proteome conservation. Such lines indicate regions of genetic similarity and synteny. Thus, phage genomes within a cluster carry homologous genes in the same functional order and so have similar virion structures, transcription pattern and lifestyles. For example, no *Enterobacteriales* cluster contains convincingly temperate and lytic phages; however, some *Actinobacteria* clusters contain both and their transcription patterns are very similar. This suggests that at least some types of phages do not easily move between these two major types; however, a small number of *Enterobacteriales* lytic and temperate clusters have similar virion structure and assembly genes. The ES18-like and P22-like temperate phage clusters have rather divergent virion structural genes that are nonetheless syntenic with the E1-like and IME-EC2-like lytic phage clusters, respectively, indicating that a small number of ancient exchanges of large genome segments has occurred between lytic and temperate phages. We note that analysis of just the MCP has been shown to usually ($\sim 99\%$ of the time) reflect the cluster to which a phage belongs, indicating that horizontal MCP exchange between clusters is in fact quite rare. The exceptions to this rule are phages that have acquired an MCP gene from a more distant relative outside of its cluster. The dot plot approach also reveals hierarchical relationships, and we use the term "subclusters" for more highly related groups (long, strong diagonal similarity lines, generally with $> 80\%$ ANI) within clusters. The higher level "superclusters" include groups of phage clusters that have syntenic genomes that encode homologous but more distantly related proteins without extensive nucleotide sequence similarity (less than 50% of the genomes are similar by dot plot, generally with $< 50\%$ ANI) (Fig. 1). We use this cluster terminology in this review.

A weakness of the dot plot cluster method is that it is difficult to quantitate relationships. Nonetheless, it succeeds in placing nearly all phages into useful and informative groups. However, there are a few known cases where a given phage is about half related to one cluster and half to another within a supercluster. These are apparently rather recently formed hybrid phages between members of two closely related clusters, and the dot plot method shows this clearly. For example, among the *Enterobacteriales* phages (see below) about half of the phage FSL_SP-016 genome (Accession No. KC139516) is similar to the BP-4795-like cluster and about half is similar to the ES18-like cluster. Thus, classification by the dot plot method can in rare instances be somewhat ambiguous, but it provides a platform to easily recognize and understand such "hybrid" phages.

We note that the two most common terminologies for discussing phage relationships, International Committee on Taxonomy of Viruses (ICTV) defined species and genera and dot plot defined clusters, are not unrelated or mutually exclusive in that they both rely on these whole genome nucleotide/proteome methods. The taxa put forward by the ICTV for phage classification (phylum, class, order, family, genus and species) are useful, but since they typically utilize whole genome averaging methods they do not emphasize the mosaic nature of phage genomes in the way dot plots do (see below). Discussion regarding what comprises a phage 'species' and what classification scheme is most useful remains lively.

Strategies for Studying Phage Diversity

Phage diversity can be studied by two opposing tactics, a "top down" strategy where total extant phage sequence diversity is analyzed in environmental samples and a "bottom up" strategy where individual phage genomes are compared. The enormous diversity of phages means that to be meaningful the latter must examine a very large number of individual "authentic" phages or be limited to phages that can infect a given bacterial taxon. Again, each approach has strengths and weaknesses. The top down methods depend on metagenomic analysis of environmental samples which can include mining total metagenomic sequence libraries for sequences that are similar to known phages or isolation and sequencing (not propagation) of purified virion fractions of such samples. The major advantage of this type of approach is that in theory it can see the entire expanse of phage diversity. However, it also has weaknesses; for example it is difficult or impossible to recognize completely novel phages, RNA phages are overlooked when only DNA is sequenced, not all virion types purify in the same fractions, some virions may be unstable and hard to purify, whole genome sequences have been difficult to obtain in high numbers, any complete genomes assembled from such

Fig. 1 Hierarchical phage classification by dot plot. Six representative phage genomes in the *Enterobacteriales* T1 supercluster phage genomes and four T7 supercluster genomes are compared with Gephard and a window size of 10. Phage names are shown at the left and top of the figure. The T1 supercluster genomes fall into a single cluster since they all have strong or weak, long diagonal similarity lines. They comprise three (previously named) subclusters whose members form strong lines within the subcluster and weak lines between subclusters. The four members of the T7 supercluster form the T7-like and SP6-like clusters with no diagonal lines between them. Each of these clusters contains two members of a single subcluster. The T7- and SP6-like clusters are members of the same (T7) supercluster because their genomes are highly syntenic when the proteins encoded by their genes are analyzed (*i.e.*, they have very similar gene orders, transcription patterns and molecular lifestyles).

samples are likely composites of similar individual phages, it can be difficult to know the bacterial host species of the phage genomes discovered, phage virions can contain DNA from their bacterial hosts, and, finally, interesting findings cannot be easily be studied in more depth because of the inability to find and propagate the actual phages that correspond to the sequences of interest.

On the other hand, the bottom-up strategy of isolating phages on particular hosts and studying them has the major advantage that the hosts are known and phage features can be studied in as much detail as desired. Its disadvantages are as follows: phage types may vary across the bacterial spectrum, so many phages that infect many different hosts must be studied to determine the complete extent of phage diversity, some phages may be difficult to propagate in the laboratory and so may be missed, and most importantly one is entirely dependent upon random chance for the discovery of new phage types so it is very hard to know rigorously when all extant varieties have been found; even for *E. coli* and *Salmonella enterica*, two of the bacterial species for which phages are best understood, new phage clusters or types are still being discovered.

Examples of Phage Diversity

Top Down Studies

Human phageome

A myriad of top down metagenomic virome and phageome analyses from such diverse sources as human, termite and sea squirt guts, ocean water and lake bottom sediment have shown that phages are spectacularly diverse and that this diversity has not yet been fully described. The majority of top down phage diversity studies have been human-centric or focused on the marine environment. These two kinds of samples provide evidence that phage diversity varies dramatically in different ecological niches. For example, temperate phages appear to be more prominent in the human gut, while lytic phages appear to be more prominent in the marine environment. The temperate phages of the gut, especially in their prophage state, influence human health through the expression of their lysogenic conversion genes within their bacterial hosts, providing novel functions and capabilities, including defense against the human immune system. Initial human phageome studies suggested a great diversity among individuals, but more recent deeper sequencing and better analysis methods have allowed the identification of bacteriophages that are common among many human individuals, including the crAssphage family. The latter is a novel group of viruses that infect at

least in some cases *Bacteroides* hosts and can comprise up to 90% of the human gut virome, making them the most ubiquitous and abundant phages found in human samples to date. These and additional studies support the presence of a stable, diverse and unique personal phageome as well as a population of phages that are highly conserved across most healthy individuals.

Marine phageome

In contrast to the primarily temperate human phageome, the marine phageome is reported to be primarily lytic. With an estimated concentration of 10^8 phage per mL of ocean water, many marine virome metagenomic studies have been performed from geographically diverse sources. These studies report a staggering diversity in that 87%–93% of putative sequences in oceanic “virus preparations” lack similarity to known reference sequences. This lack of similarity also hampers assembly of whole genomes, and therefore, estimates of diversity are primarily derived from analysis of viral protein clusters. In 2015, the analysis of metagenomic marine data suggested a global virome consisting of less than 3.9 million “protein clusters”, and revealed variation according to depth, distance from shore and season of the year. Genetic flow appears to travel from the ocean surface to the deep in that core (ubiquitous) protein clusters are enriched on the ocean surface, while greater diversity is present in areas where the ocean is not illuminated by the sunlight (the aphotic zone). Relatively few whole genome sequences of authentic marine phages have been reported (482 complete sequences as of 2015, of which only 274 have known hosts), and these have been isolated on only a few representative bacterial hosts (22 genera of the 10^6 estimated in the ocean), making phage-host relationships relatively unstudied. This is rapidly changing, however, with advanced methods for bacterial culture, single-cell sequencing of bacteria and the phages that have infected them, and phage-tagging strategies. Although many of the fully sequenced marine phages represent novel types, some have similarities to the *Enterobacteriales* T4-like, T7-like and N4-like non-marine phage clusters.

Bottom Up Studies

Two large diversity studies

The bottom up method has been utilized on a large scale in only two out of the nearly 200 currently defined bacterial orders, the Gram negative order *Enterobacteriales* and the Gram positive order *Actinomycetales* (currently being expanded to include other orders in the *Actinobacteria* phylum). Analyses of these two large phage groups have largely relied on the dot plot and shared gene approaches to define phage clusters. Over 1150 genomes of authentic phages that infect the *Enterobacteriales* and about 2700 that infect the *Actinobacteria* have been sequenced. These *Enterobacteriales* phages were independently isolated and sequenced by a large number of diverse researchers around the world and deposited in the GenBank database. They currently form 82 clusters of which 23 are singleton clusters (clusters with only one phage). The *Actinobacteria* phages were isolated through the Howard Hughes Medical Institute (HHMI) Science Education Alliance Phage Hunters Advancing Genomics and Evolutionary Science (SEA PHAGES) program and are available at NCBI GenBank and website available at: “Relevant Websites section”. They currently form 182 clusters of which 62 are singleton clusters. The significant number of singleton clusters strongly suggests that the diversity of both these large sets of phages remains quite incompletely described. Although the order *Enterobacteriales* is a narrower taxonomic unit than the phylum *Actinobacteria*, the current average number of phages examined for each cluster defined is quite similar, about 14 and 15, respectively. Thus, at this still early stage of the analysis of tailed phages, this aspect of diversity appears to be rather similar in these two very disparate bacterial taxa, and we project that it may well be similar across all the *Bacteria* domain. Nonetheless, currently these bottom up studies still suffer from the fact that a very small fraction of extant phages have been analyzed, so future studies could change current views.

The *Enterobacteriales* tailed phage example

As an example of the rapidly expanding nature of the study of phage diversity, the initial 2014 analysis of the *Enterobacteriales* phages in GenBank included 337 complete bacteriophage genomes sequences. These phages were isolated on 18 bacterial host genera and 31 species and comprised 56 separate clusters (32 lytic and 24 temperate). There are currently about 1150 *Enterobacteriales* phage genomes in GenBank (a 3.4-fold increase in 4.5 years) isolated on 25 host genera and 50 species, and these fall into 82 clusters (50 lytic and 32 temperate). As further indication of the incomplete nature of our current understanding, we note that the bacterial order *Enterobacteriales* currently contains 55 genera (and at least 30 more have been proposed for membership), so phages that infect less than half of this taxon’s genera have been examined. The number of related phage clusters will certainly grow until phages are included that infect all its genera.

As described above, members of a given phage cluster have very similar molecular lifestyles, but the various *Enterobacteriales* tailed phage clusters, nonetheless, have internal diversity, the extent of which can vary dramatically. For example, one of the least diverse clusters is at present the jumbo phage Ea35-70 *Myoviridae* cluster comprised of nine *Erwinia* phages that form a single subcluster level group of highly related phages (>94% ANI with genome sizes that range only from 271 to 275 kbp). These correspond to the ICTV designated Agrican357 virus genus. Other clusters are comprised of more diverse phages, such as the SPN3US-like *Myoviridae* cluster whose 18 known members infect four different host genera including *Escherichia*, *Salmonella*, *Cronobacter* and *Erwinia* and show striking diversity with some members sharing less than 37% ANI. These SPN3US-like phages are diverse even when isolated from a single host in that the 12 *Erwinia* phages form seven different subclusters.

Superclusters designate distant phage relatives with similar protein and content order but little nucleotide similarity (above). Analysis of the *Enterobacteriales* phage clusters reveals at least seven supercluster level groups that contain multiple clusters. The

most commonly sequenced *Enterobacteriales* bacteriophages are members of the T7 supercluster, which is comprised of nine clusters that contain 191 phages that infect 18 host genera. No doubt these phages are very successful in the environment, however, this may reflect ease of propagation in the laboratory rather than ecological domination. The remaining six groups that contain multiple clusters are the lytic superclusters typified by phage N4 (2 clusters, 28 phages, 7 host genera), SETP3 (3 clusters, 88 phages, 8 host genera) and rV5 (2 clusters, 46 phages, 6 host genera) and the temperate superclusters typified by lambda (25 clusters, 169 phages, 15 host genera), P1 (2 clusters, 7 phages, 2 host genera), and P2 (2 clusters, 25 phages, 6 host genera). Thus, superclusters of both lytic and temperate types are internally very diverse, infecting multiple hosts with a wide diversity of phage clusters.

A closer look at diversity within the *Enterobacteriales* T7 supercluster reveals gene synteny with minor variations and conservation across all eight of its clusters for key early genes (host restriction proteins, DNA polymerase and RNA polymerase), middle genes (DNA metabolism functions and lysozyme) and late genes (virion structure and assembly). In general, within each of these clusters member phages share >50% of their proteome, whereas the proteome conservation is often ~30% between these “closely-related” clusters. Phages in the even more diverse lambda supercluster also contain conserved modules of function including the following genes in the same order (with only a few minor exceptions): terminase and head assembly genes, followed by tail assembly genes, lysogenic conversion genes, integrase and homologous recombination genes, the early gene transcriptional control genes (anti-terminator [N], prophage repressor [CI], cro repressor and CII transcriptional activator), DNA replication, “nin region” genes, late gene transcriptional antiterminator and lysis genes. Nearly every lambdoid cluster contains a unique, very different set of head assembly genes; the only exceptions are the P22-/APSE-like and lambda-ø80-/N15-like groups of clusters that have similar head assembly genes but have major differences elsewhere in the genome.

Contribution of Prophages to Phage Diversity

Although it has not been studied quantitatively, isolation of phages from the environment may sometimes underestimate temperate phages. For example, nearly all of the *Enterobacteriales* “model system” temperate phages that have been studied in great depth in the laboratory (e.g., phages P1, P2, P22 and lambda) were isolated after they were released from prophage-carrying bacteria in the laboratory rather than as infectious virions from environmental samples. Perhaps they spend most of their time as prophages and less as virions? This may be less true for the *Actinobacteria* phages, as many environmental temperate phages have been isolated that infect that host taxon. Bacterial genomes are known that harbor >15 prophages, and in one of the few systematic studies in this area it was found in 2016 that analysis of 3298 *Salmonella* genomes identified 9371 tailed phage prophages that belonged to the 20 temperate *Enterobacteriales* phage clusters that had been defined at the time. Prophages are clearly very abundant and diverse. It is very likely that unrecognized prophages that belong to currently undiscovered clusters are also present in bacterial genome sequences, but because of the great diversity of tailed phages no computer search engine currently exists to rigorously discover and classify all of them. Clearly, since bacterial cells are thought to be about 10% as abundant as phage virions in the environment, the number of tailed phage prophage DNAs on Earth is likely within about an order of magnitude of the number of free virions, and they represent a still rather poorly understood source of phage diversity.

Phage Diversity and Horizontal Exchange of Genetic Information

The Nature of Horizontally Exchangeable Mosaic Section Alleles

Many reports have emphasized credible examples of past horizontal exchange of genetic information amongst the tailed phages, and although such exchange does not increase the number of phage gene types, it increases the diversity of gene combinations, increases the diversity within the participating clusters, provides opportunity for further gene divergence and spreads phage genetic information across the *Bacteria* domain. The frequency of such horizontal exchange events between phage types is not known, but it is not high enough to homogenize all such genomes or even disrupt the clear division of phages into clusters. Comparison of phages within any cluster typically shows patchy similarities with regions of high similarity interspersed with regions that are very different. Such genomes are said to be “mosaically related” and the different patches are thought to have arisen through horizontal exchange mechanisms. Genome mosaicism was recognized early in the study of *E. coli* phage lambda and its relatives and has since been shown to be present to varying degrees in most *Enterobacteriales* phage clusters. In general, temperate phage clusters appear to exhibit more extensive mosaicism than virulent ones, and mosaicism has been studied in most detail in the phage lambda.

All members of each supercluster have syntenic genomes where genes with parallel functions have the same chromosomal order and have similar overall transcriptional gene expression patterns. At present genomes of about 170 authentic phage (ignoring thousands of related prophage sequences) members of the *Enterobacteriales*-infecting lambda supercluster have been completely sequenced, and these are currently divided into 25 clusters. Comparison within each cluster shows much more overall similarity than comparisons between clusters; however, even phages within a cluster often show substantial mosaicism, and Fig. 2 shows, as an example, the relationship between two typical members of the temperate phage P22-like cluster within the lambda supercluster. This cluster has been studied in detail and contains at least 25 exchangeable mosaic segments or modules within the cluster of 15 virion assembly genes that make up about half of their genomes. Such segments can encode parts of genes, whole genes or clusters of genes.

Fig. 2 Phage genome mosaicism. The typical mosaicism present in the genomes of phages P22 and Emek in the P22-like cluster within the phage lambda supercluster is shown in the dot plot (Accession numbers BK000583 and JQ806763, respectively; plot was produced by DNA Strider with a scan window threshold of 17 identities per 23 bp). The transcription pattern and location of functional gene clusters of P22 are indicated above the plot. Below the plot, the two-domain tailspike proteins are diagrammed with white N-terminal domains indicating their strong similarity and two shades of gray indicating that their C-terminal receptor-binding domains have no recognizable homology. At the bottom, the aligned nucleotide sequences at the mosaic boundary between the two phage's tailspike genes' N- and C-terminal domains are shown (translation is from left to right). We note that P22 and Emek infect *Salmonella* serovars Typhimurium and Haardt, respectively. These two *Salmonella* serovars have very different surface polysaccharides, and the C-terminal polysaccharide-binding tailspike domains are essentially unrelated in amino acid sequence.

Three different types of diversity exist within allelic sets of mosaic modules, and the mosaic section that encodes the P22 tailspike C-terminal receptor-binding domain demonstrates this as follows: (1) Some such alleles are divergent but retain recognizable protein sequence similarity (*e.g.*, phage P22 (Accession No. KR296686) and Det7 (Accession No. KP797973) tailspikes); (2) some are ancient homologs that have diverged to the point that recognizable sequence similarity is lost but they retain

similar protein folds (e.g., P22 and Sf6 (Accession No. AF547987) tailspikes); and (3) others are unrelated and have different protein folds that serve the same function (e.g., P22 and CUS-3 (Accession No. CP000711) tailspikes). The number of different alleles that are known for the various mosaic modules along the genome is highly variable. There are, for example, three major sequence types of P22-like major capsid protein, but there are many more types of tailspike C-terminal domain which binds the virion to its polysaccharide receptor and so is the primary determinant of host specificity; each of its >70 known very different sequence types in the P22-like phages is responsible for binding a different polysaccharide. Thus, there can be very extensive diversity even within a phage cluster.

How did Genome Mosaicism Arise?

The patches of similarity and difference (mosaic modules) appear to be the result of recombination after rare horizontal exchange, usually between divergent members of a cluster or supercluster. A few short homologous syntenic sequences have been found between mosaic modules (often transcription terminators) that could allow homologous recombination to create new combinations of adjacent mosaic module alleles; however, no such common sequences have been found between most adjacent modules. Fig. 2 shows that module boundaries are often very abrupt. Thus, generation of new combinations of adjacent alleles (i.e., new mosaic section boundaries) is likely usually due to random nonhomologous recombination. The probability of generation of new combinations by random processes is clearly very low, but it does not seem unreasonable since phages are so abundant that random processes, even if they are infrequent, might be able to generate many different nonhomologous recombinants over evolutionary time. The probability of success is increased within a supercluster of phages by the fact that such phages have the same gene order, so a single rare non-homologous recombination event that happens to occur at the same location between two exchangeable DNA (mosaic) sections of two such phages will result in a genome that contains all the modules that are necessary to be a functional phage (i.e., multiple recombination events are not required). If such a rare recombinant happens to have an evolutionary advantage it will survive and thrive. Once such a nonhomologous recombination event has created a new module boundary, new combinations of nonadjacent module alleles can arise rapidly by homologous recombination within a module allele that two phages have in common.

These exchangeable modules appear to be evolutionarily shuffled more or less randomly within clusters, suggesting that each unit may have evolved to function at least semi-autonomously. This idea is supported by the fact that where information is available, intragenic boundaries coincide with protein domain boundaries, and laboratory construction of new combinations of modules (not previously observed in nature) usually creates a functional phage.

Genetic Exchange Among Superclusters

Rare successful recombination events have also clearly occurred between phages that belong to different superclusters, and most of these involve tail fibers or tailspikes. Two well studied examples are the tailspikes of phages P22, 9NA (Accession No. KJ802832) and Det7 and the long tail fibers of phages T4 (Accession No. AF158101) and lambda (Accession No. J02459). The first three phages are members of different superclusters in the *Podoviridae*, *Siphoviridae*, and *Myoviridae*, respectively. They have essentially no overt nucleotide sequence similarity except between C-terminal domains of the tailspikes that bind to the O-antigen polysaccharide on the surface of *Salmonella enterica* serovar Typhimurium. The second pair of phages above also reside in very different superclusters (a lytic and a temperate cluster) and are members of the *Siphoviridae*, and *Myoviridae*, respectively. They have similar long tail fiber genes, and the lambda fiber can functionally replace the T4 fiber. It seems reasonable that these islands of similarity in otherwise extremely distantly related phages must have been horizontally transferred by very rare nonhomologous recombination and have given the recipient phage access to a new, naïve host that allowed them to flourish.

Phage-host Relationships and Phage Diversity

Phage Cluster-Host Species Relationships With the *Enterobacteriales*

The relationship between phage clusters and their hosts must reflect their evolutionary history. But do phages simply co-evolve with their hosts over long evolutionary periods so that each phage cluster infects a single host taxon (species, genus, etc.), or is jumping to a new taxonomically very different host sufficiently common to disrupt this kind of simple co-evolutionary descent? This aspect of phage diversity is very poorly understood at present. The following paragraphs describe our current knowledge in this arena.

When phage cluster membership is compared with the hosts on which the phages were isolated, there is one strong conclusion. Very few phages from outside the *Enterobacteriales* have been found that clearly fall within *Enterobacteriales* phage clusters, so phages appear to jump between distantly related hosts quite rarely. We suppose that there are at least two major factors that limit such jumps across large host taxonomic chasms. (1) Virions recognize specific bacterial surface receptor molecules and disparate hosts are unlikely to have very similar surface features, so delivery of virion nucleic acid into very distantly related cells should be an uncommon event. (2) Perhaps more importantly, phages must be evolutionarily tuned to optimally infect their primary hosts

Fig. 3 The N4 supercluster dot plot. Representative N4 supercluster phages are included in the dot plot. Thin red lines separate genomes, thick red lines separate subclusters, and blue lines separate clusters. Clusters and host genera are indicated at the right and thick vertical colored lines there indicate the taxonomic order to which the hosts belong. Note that the orders *Enterobacteriales* and *Pseudomonadales* are in the *Gamma* *Proteobacteria* class, and *Burkholderiales* is in the *Beta* *Proteobacteria*.

in terms of the many ways in which their encoded proteins interact with host components, for example during the commandeering of host macromolecular synthesis machinery. Such tuning would mean that phages would likely infect distantly related bacteria with suboptimal efficiency and so would not compete well with the native phages there.

On the other hand, any given non-singleton *Enterobacteriales* phage cluster often contains phages that have different hosts. This suggests that either phages are more frequently jumping between closely related hosts, or that co-evolution of phages and hosts during host species separation has not driven the phages into different clusters. For example, *Enterobacteriales* clusters with more than four member phages often have hosts from multiple genera that are typically but not always within one family. *Mycobacterium smegmatis* phage Patience (Accession No. JN412589) is a counterexample of an unusual phage that may have switched to a very different host relatively recently. Nonetheless, closely related phages (phages that belong to the same subcluster) often infect the same host. Our 2014 analysis found that 78% of the non-singleton subclusters were populated by phages that infect a single host genus. Thus, there appears to be a strong tendency (but not a requirement) for closely related phages to infect closely related hosts.

We emphasize that phage-host relationships must always be viewed with some caution because of inherent complicating issues. The most prominent issue is that the full host range of most phages is not known. Rigorous determination of the full host range of any phage would require plaque assay or other tests for successful infection on an impractically large number of potential hosts. Therefore, careful and extensive host range studies are rarely performed due to the technically difficult, labor intensive and time consuming nature of testing a wide variety of bacteria, so nearly all host range studies have been limited to a small number of closely related potential hosts, which may not be indicative of true host range (see below).

Narrow and Wide Host Range Phages

Phages have a reputation for having very narrow host ranges, and many phages are indeed very host specific. Some phages like those whose virions adsorb to bacterial surface polysaccharides often successfully infect only a small fraction of cells in their host species. For example, phages such as *S. enterica* phage P22 and *E. coli* phage CUS-3, only adsorb to hosts whose surface polysaccharide has a repeating -mannose-rhamnose-galactose- unit or is polysialic acid, respectively. A few phage virions have up to four or five different tailspikes that allow them to adsorb to, and thus infect, hosts with several different surface polysaccharides. *Salmonella* and *Escherichia* strains are known that have over 200 different surface polysaccharides, so even phages that recognize several such receptors have rather narrow host ranges restricted to a small fraction of these species. At the other end of the scale there are reports of very broad host range phages that can infect quite disparate hosts, but “broad host range” is a poorly defined term that is commonly used to indicate the ability to productively infect many different strains within a species or multiple

relatively closely related species. Nonetheless, a few phages have been reported that are able to infect hosts from two different bacterial orders, *Pseudomonadales* and *Enterobacteriales*, within the class Gamma Proteobacteria (e.g., EMCL-117-like phage øFenriz, Accession No. KT254133), two different orders, *Chroococcales* and *Synechococcales*, within the phylum *Cyanobacteria* (T4-like phage Syn9, Accession No. NC_008296), and even two different bacterial classes, *Alpha* and *Beta* Proteobacteria, within the phylum *Proteobacteria* (phage P14, Accession No. KX660669). One study even suggested some phages are capable of infecting species across several bacterial phyla including *Proteobacteria*, *Actinobacteria* and *Bacteroidetes* (phages øFenriz and close relatives). Such reports of successful infection of extremely distantly related hosts by a single phage species are tantalizing but very rare and should be regarded with caution until the details of infection of the disparate hosts have been described. Nonetheless, if true such phages could be vehicles for spreading diverse phage genes across the bacterial spectrum.

Finally, we re-emphasize that phages from a given cluster are often able to infect different bacterial hosts, especially if the hosts are not very distantly related, indicating that particular lifestyles do not necessarily restrict phages to particular hosts within the *Enterobacteriales*. Fig. 3 shows this for the *Enterobacteriales* phage N4 supercluster, where members are known that infect seven different *Enterobacteriales* genera, *Escherichia*, *Shigella*, *Salmonella*, *Klebsiella*, *Enterobacter*, *Erwinia* and *Pectobacterium*. For example, *Escherichia* phages EC1-UPM (Accession No. KC206278), IME11 (Accession No. NC_019423) and G7C (Accession No. NC_015933) are very close relatives, while *Escherichia* phage Pollock (Accession No. KM236242) is quite different. On the other hand, *Klebsiella* phage Pylas (Accession No. MH899585) is more closely related to phage Pollock than it is to the other *Klebsiella* phage KP8 (Accession No. MG922974) in this group. Although the relationship of most of the phages with hosts outside the *Enterobacteriales* have not yet been compared in detail to all the *Enterobacteriales* phages, a few phages have been identified from other orders in the *Gamma-proteobacteria* class and even other classes in the *Proteobacteria* phylum that fall within the *Enterobacteriales* clusters. For example, Fig. 3 also shows that *Pseudomonas* phage Inbricus (*Pseudomonadales*, *Gamma* Proteobacteria; Accession No. MG018928) and *Achromobacter* phages øAxp-3 and JWDelta (*Burkholderiales* order in *Beta* Proteobacteria; Accession Nos. KT321317 and KF787094, respectively) fall within the N4-like cluster, while other *Enterobacteriales* phages CB1 and Nepra form a separate CB1-like cluster within the N4 supercluster. Similarly, other “outside” phages fall into the *Enterobacteriales* T4-like, T7-like and P2-like clusters or superclusters. Thus, similar molecular lifestyles (superclusters) can extend at least as far as across the *Proteobacteria*, and “T4-like” phages that infect the *Cyanobacteria* phylum suggest it may extend much further. It remains to be seen if such broad reaches are common or exceptions.

Summary

Bacteriophages, like all viruses, are certainly very ancient and appear to have arisen independently multiple times; for example, virions can contain single-stranded RNA or DNA or double stranded RNA or DNA, and the proteins that form the virion’s protective coats are present in different phage types with at least five unrelated polypeptide folds. The dsDNA tailed phages are extremely abundant in the environment and their diversity has been studied in most detail through comparison of whole genome sequences, so this discussion focused on their diversity. Both top down and bottom up methods have shown that the tailed phages are extremely diverse. Multiple types (called clusters) of tailed phages exist that infect essentially all bacterial species that have been examined, and different phages within such a cluster often infect different (but almost always closely related) host species. The number of bacterial species of Earth is not known, but estimates have ranged widely from millions to billions, so the number of tailed phage types or clusters is likely this enormous as well. In addition, very substantial diversity exists within each phage cluster. Thus, phages are almost incomprehensively enormously diverse in general features as well as details, and many of these are yet to be discovered.

Genetic Mosaicism in the Tailed Double-Stranded DNA Phages

Welkin H Pope, University of Pittsburgh, Pittsburgh, PA, United States

© 2021 Elsevier Ltd. All rights reserved.

Glossary

BLAST Basic Local Alignment Search Tool. Algorithm that identifies related nucleotide or protein sequences using local alignments, available at NCBI.

Capsid Protein shell that surrounds the genetic material of a phage, in the Caudovirales, the capsid is twenty-sided – icosahedral, and may be either isometric (all sides are the same length) or prolate (elongated).

Caudovirales In formal phage taxonomy, Caudovirales (“tailed viruses”) is the name of the Order of phages that use double-stranded DNA as genetic material; enclosed in a protein capsid and possessing a protein tail that is used to recognize the host cell and deliver the DNA from the head.

Circularly permuted Describes phage genomes from phages that use the headful packaging strategy; these phages do not have a defined start or end to their genome, but instead package DNA from a long concatemer of the genome sequence. The DNA is cut when the phage head is “full”, and includes more than 100% of the genome sequence resulting in identical sequences at the end of each piece of DNA within a phage head and each virion containing the complete set of genes with in the genome, yet each individual virion contains a different chromosomal sequence.

Direct repeat Property of some phage genome ends, in that the same DNA sequence is found at both the beginning and end of the piece of DNA within the phage head. Allows for circularization of the phage genome via homologous recombination after injection into the host cell, as well as for linear multimer concatemers.

Endolysin Phage encoded enzymes that cleave the bacterial cell wall from within, aiding the release of the virions at the culmination of the lytic cycle.

Exclusion Refers to the mechanism by which a cell prevents infection of phages via modification of cell surface proteins, preventing phage attachment and DNA injection.

Genome The complete DNA sequence of an individual phage.

Host A cell that a phage can infect and propagate within.

Host range The different bacterial strains that a specific phage can infect.

Identity Sequences that are identical.

Immunity Refers to the mechanism by which a cell is resistant to phage infection via expression and binding of an immunity repressor to the invading phage DNA.

Immunity repressor DNA binding protein encoded by the phage genome that prevents expression of phage genes involved in the lytic cycle. The immunity repressor is continually synthesized during lysogeny.

Integrase Enzyme that promotes homologous recombination of the prophage and the bacterial genome at attachment sites with the result of a stable single piece of DNA.

Lysogenic The cycle in which some phages (temperate phages) delay the lytic cycle after DNA injection, and

instead exist within a host cell as a quiescent piece of DNA (a prophage).

Lysogen-y A cell that contains a prophage is a lysogen, and exists in the state of lysogeny.

Lytic Describes the cycle of phage infection from DNA injection, through phage genome replication, synthesis and assembly of virions, and burst of the host cell. Also describes phages that undergo the lytic cycle (“lytic phages”).

Myoviridae The taxonomic Family name for the contractile tailed phages.

Pham (or phamily) Group of related protein sequences as calculated by the program Phamerator.

Plaque A clearing in a lawn of bacteria due to the presence of an initial single virion that subsequently underwent multiple rounds of the lytic cycle, killing the host cells in its proximity.

Plasmid An additional piece of DNA within a host organism, smaller than the larger genome, that is replicated and passed down to daughter cells during division.

Podoviridae The taxonomic family name for the short tailed (extensible tailed) phages.

Prophage The repressed genome of a temperate phage found within a host cell.

Recombination, homologous and non-homologous Process by which two pieces of DNA break and swap ends; such that pieces “A–B” and “C–D” become “A–D” and “C–B”. Homologous recombination occurs between identical sequences with the strands and happens more frequently than non-homologous recombination which requires no sequence identity.

Resistant A cell that is not susceptible to phage infection.

Similarity Sequences that show conservation of related amino acids in corresponding positions, even if the sequence is no longer identical.

Siphoviridae The taxonomic Family name for the non-contractile tailed phages, also called the flexible-tailed phages.

Synteny The conservation of gene order observed within phage genomes.

Tail Protein structure that mediates host recognition and DNA delivery in the tailed phages. Tails are comprised of multiple different proteins and are found in a number of morphologies.

Tail fiber The long, thin, extended proteins attached to the tail tip that are the primary mechanism by which a phage binds to its host cell.

Tape measure The protein that makes up the core of the flexible-tailed phages, the length of the tape measure is directly proportional to the length of the phage tail.

Temperate Describes phages that are capable of delaying the lytic cycle after their DNA is injected within the host cell; instead the phage undergoes the lysogenic cycle in which DNA is replicated within the cell (called lysogens) and passed onto daughter cells after cell division. When host cells are stressed, the lytic cycle may be induced.

Terminase ATP-driven DNA packaging motor encoded by phage genomes. By convention, the terminase gene is frequently assigned position 1 in the genomes of flexible-

tailed phages; in the short-tailed podoviridae, the terminase is found towards the right end of the genome.

Virion An individual virus or phage particle.

Introduction

Bacteriophages – or phages, the viruses of bacteria – are the most numerous biological entities on the planet, with an estimated global population of 10^{31} , and a turn-over time of several days – these numbers are based on measurements taken by the Colwell lab in 2000, and Suttle lab in 2007. Phages are comprised of nucleic acid – dsDNA, ssDNA, dsRNA, or ssRNA – surrounded by a protective proteinaceous shell. The majority (over 90%) of the sequenced phage isolates in the non-redundant “Nucleotide” collection in GenBank as of February 2019 are members of the Caudovirales (also called the tailed phages), these phages use dsDNA as genetic material surrounded by an icosahedral “head” (or capsid), and at a single vertex is attached a complex, multi-protein structure called a “tail” which mediates recognition of the bacterial host. Tailed phage morphology broadly falls into three groups and is the basis for the taxonomic classification of these phages: the Myoviridae, or contractile-tailed phages; the Siphoviridae, the non-contractile or flexible tailed phages, and the Podoviridae, the short-tailed phages. Numerous isolates of each morphological type have been recovered from a variety of hosts and habitats; comparatively fewer of these have had their genomes sequenced and analyzed using tools to predict the location and functions of their genes, and to determine how similar they are to each other. Comparisons of the genome sequences in smaller, host specific-sets, as well across the broad collection as whole, have illuminated a number of properties of phage genes and genome sequences conserved throughout the morphological types, as well as allowed scientists to gain insights into global viral genetic space. This includes the property of “mosaicism” – as phage genomes are collections of individual genes with separate evolutionary histories – much like a mosaic is a piece of art comprised of many different individual tiles. Independently, the tiles – or genes – are less meaningful, but together, the tiles form a single large mosaic picture, just as phage genes collectively encode the instructions for the life cycles of a single phage.

Evidence for Genome Mosaicism Before the Advent of DNA Sequencing

The mosaic nature of tailed bacteriophage genomes was first described in the hybridization studies of DNA from *Escherichia coli* phage lambda and its relatives in 1971. DNA from these phages was melted to single strands, mixed, and allowed to re-anneal and form heteroduplexes; these were examined with transmission electron microscopy, and the lengths and locations of the bound, complementary sections versus unhybridized pieces carefully mapped. It was readily apparent that there were portions within each of the phage genomes that had sufficient identity to form stable duplexes with the others interspersed with regions of non-identity; and that these sequences were not uniformly distributed across the different phage genomes. Some phages shared certain portions of their genomes; other portions of their genomes were shared with other phages that did not contain the first segment.

Subsequent genetic studies of the *Salmonella* phage P22 identified genes and regions of genome organization in common with the *E. coli* lambdaoid phages – surprising investigators who had grouped the P22-like phages with the *E. coli* T7-like phages based on their shared short-tail morphology. These observations of shared genetics between morphologically dissimilar phages, among others, led Susskind and Botstein (1978) to propose a method of phage genome evolution based on swapping of modules of genes; suggesting that this was accomplished by homologous recombination – breaking of the two DNA strands at identical sequences followed by rejoining to the other phages’ genome, creating a new overall sequence. They proposed this was promoted by the existence of short, identical “linker” sequences flanking related modules; such a mechanism could result in the observed mosaic patterns between genomes. In phages in which no linker sequences could be identified, they proposed that periodic loss of linker sequences through mutation could occur, thus preventing their identification in sequence comparisons.

DNA Sequencing Illuminates Properties of Bacteriophage Genomes

With the advent of DNA sequencing, phages were an obvious target due to their short genomes and tractability as a model system; and indeed, the first complete genome sequence of any entity reported belonged to the phage phiX174 by Sanger (1977), with the larger phage lambda following in 1983. Subsequent genome sequencing and comparative analyses through the 1990s revealed sequence similarity and shared genome architecture from phages across of a variety of hosts, including Gram negative *E. coli* and *Salmonella* phages as well as Gram positive *Mycobacterium* and *Streptomyces* phages. Indeed, in 1999, sufficient phage genomes had been fully sequenced such that Hendrix *et al.* proposed that all tailed phages were related through common ancestry, had access to a global pool of genes; and that the variation of identical sequences flanked by unrelated sequences, mosaicism, was a universal property of phage genomes. Interestingly, the mosaicism was not distributed at random through the genomes, but instead mapped most often to gene boundaries, such that intact genes were shared between otherwise unrelated genomes. Nor was

the mosaicism limited to a few mobile elements, such as transposons, found across a large number of genomes, but was identifiable throughout all regions and genes within phage genomes.

With the analysis of additional phage genome sequences, genetic mosaicism continued to be observed throughout phages of different hosts and morphologies, and it became evident that homologous recombination between linker sequences facilitating the exchange of genetic modules could not be the primary driver behind genome diversity and evolution, as multiple versions of genes with significant sequence similarity were found across otherwise unrelated phage genomes. Instead, Hendrix *et al.* (1999) proposed that the driving force behind the mosaicism present in phages genomes must be non-homologous recombination. This argument was based on the sheer magnitude of the numbers involved, with a rationale along these lines, with 10^{31} phage virions on the planet, and a predicted 10^{23} productive infections per second, a certain number of those infections would be co-infections, bringing related or unrelated phage genomes into direct contact with each other inside the same host cell. Within those co-infections, if a fraction of those underwent a nonhomologous recombination event, there could be on the order of 10^{16} events per second. The majority of these non-homologous recombination events are likely to produce non-viable progeny – if you swap the center of your capsid gene for the middle of the other phage's DNA polymerase gene, both progeny will both be unable to produce new phages in the next generation – and so, the recombination events that produce viable progeny will be more likely to occur at gene or protein domain boundaries at a rate of approximately 10^9 per second, – thus leading to the observed pattern of genetic mosaicism in phage genomes.

Comparative Genomics of Complete Bacteriophage Sequences Shows Diversity and Mosaicism

As DNA sequencing costs dropped, more phages were completely sequenced; including groups of *Lactococcus* phages and *E. coli* phages. A detailed analysis of the genomes of lambda-like *E. coli* phages, including HK97 and HK022 by Juhala *et al.* (2000) demonstrated that the mosaicism present in the genomes was not limited to gene or module boundaries, even those sites were overrepresented in the reassortment of the genes between genomes. Indeed, recombination events had clearly taken place between phages within coding sequences, although these were not evenly distributed across all genes, as more events were identified between tail fiber genes, than between others, suggesting that the mechanism behind these patterns was rampant non-homologous recombination between co-infecting phages or prophages that were previously integrated in the host cell. The prevalence of mosaic events in tail fibers could be part of a mechanism to increase the rapid diversification of host range, or could be an artifact of the linear structure of the fibers – long extended proteins like tail fibers could more easily tolerate non-homologous joins than similar events in globular proteins, which could be more likely be lethal to the phage. Closer examination of genomes from phages across hosts and virion morphology demonstrated that even though nucleotide and protein sequences of the genes were unrelated, the order and location of genes within phage genomes, particularly amongst phages with shared morphologies, was conserved. This property is called “synteny”, that analogous genes appear in the same order within phage genomes.

The vast diversity of phages was illuminated by an analysis by Pedulla *et al.* (2003) of a collection of fourteen complete genome sequences from phages infecting the same host, *Mycobacterium smegmatis* mc²155. These phages were all tailed phages, and predominantly flexible tailed (two were contractile-tailed); and many of them were indistinguishable from each other by electron micrograph. However, comparative analysis of the genome sequences revealed that these genomes had *less than 50%* nucleotide sequence identity. This was a tremendous surprise to the scientific community – these phages that appeared identical under the microscope and were in direct genetic contact with each other through their ability to infect the same host did not share significant DNA sequence identity (for comparison, humans share about 60% of their genome sequence with bananas). Not only did these phages not share sequence similarity with each other, the majority of genes within phage genomes were unlike any other sequences in our sequence databases, that only 20% of the genes within a phage genome could be assigned a putative function.

The genes that could be assigned functions, both during these studies in the early 2000s and up through the writing of this article in 2019, were those that played well-characterized roles in the phage lifestyles. During the lytic cycle, after binding to a host cell, the phage nucleic acid is deposited into the cytoplasm, where it undergoes transcription, translation, and replication; the structural proteins are synthesized, the heads and tails self-assemble, DNA is packaged into the head, the head and tail are joined; and the cells are lysed releasing the new virions into the environment. Temperate phages can undergo the lysogenic cycle, during which they integrate their DNA into the host genome or circularize as a large extrachromosomal plasmid and repress their lytic functions by means of a protein called the immunity repressor; the phage DNA is then replicated by the host during normal cell division and passed on to both daughter cells. Lysogens, the cells that contain these phage genomes (called prophages) sometimes gain new abilities via genes expressed from the prophage, included those involved in host defense against subsequent infection from other phages; lysogens can also undergo induction of the lytic cycle during stress, and the prophage can excise from the host genome and begin the lytic cycle. Many of the proteins involved in these processes are phage-encoded, and can be routinely identified in phage genome sequences based on sequence similarity to those genes in other phages that have been characterized at the bench. The different branches of the Caudovirales – Siphoviridae, Myoviridae, and Podoviridae – demonstrate conservation of some genome properties with regard to genetic content as well as variations specific to their morphology; each type is broadly discussed below.

Mosaicism in the Siphoviridae

The flexible, non-contractile tailed phages, the Siphoviridae, have been isolated from all known bacterial phyla and habitats; many of the more recent large scale comparative genomics studies describe phages of the Siphoviridae. Within the genomes of the Siphoviridae (Fig. 1),

Fig. 1 Three phage genomes – *Gordonia* phages BaxterFox and Zirinka, and *Mycobacterium* phage Che9c – are compared with the program Phamerator. The letters/numbers after each phage name indicates their cluster and subcluster designation. The central ladder indicates the length and position of the nucleotide sequence, in kilobases. Genes are represented by rectangles, and colored according to protein sequence similarity; genes in white share no protein sequence similarity with any other proteins in the Actino-Draft database. Numbers within the rectangles indicate the gene numbers; numbers above the rectangles indicate pham number, the number in parenthesis indicate the number of genes within that pham from the entire database “Actino-Draft”. The direction of transcription is indicated by the placement of the rectangles above or below the central ladder; above, indicates left to right. The colors between the genomes – as opposed to the colors of the gene rectangles – indicates nucleotide sequence similarity as calculated with the program BLAST, purple represents the most similar sequences, shading to red as the least similar, and white indicates no significant sequence similarity.

synteny is evident in the order of the virion structural genes in particular; by convention, newly sequenced phage genomes are oriented such that the structural genes are on the left-side of the genome, and the gene(s) encoding the terminase, the DNA packaging motor, is one of the first, if not the first, gene. Following the terminase are genes encoding the head and tail components, specifically, the portal protein, the capsid maturation protease, the scaffolding protein, the major capsid protein, the head-to-tail connector proteins, the tail terminator, the major tail subunit, the tail assembly chaperones, the tape measure, the minor tail proteins, and the tail fiber. The number and size of the structural genes, and the conservation of their order is pervasive, from the very smallest flexible tailed phages with genomes of approximately 15 kb; to the largest, with genomes closer to 100 kb; and is observed in phages of hosts in multiple phyla, in both Gram-positive and Gram-negative bacteria, and from diverse environments. Interestingly, while the order of these genes is predominantly maintained, the larger phage genomes have more gene insertions between various structural proteins; these genes include parasitic elements like transposons, self-splicing introns, and homing endonucleases, as well as a large number of genes without identifiable functions.

Adjacent to the structural genes are the genes predicted to encode proteins involved in cell lysis, including the endolysin(s) and holin; these are followed by a central region of the genome in found only in temperate phages containing the integration cassette, including the integrase, the attP site (for “att”achment “p”hage, the DNA sequence that is identical to the integration site in the host) and the immunity repressor, which prevents expression of genes involved in lytic functions. The integration cassette region in many temperate phages is highly variable, and otherwise closely related phages can display a subset of a wide range of diverse small genes in this region. These genes are expressed from the prophage during lysogeny, and at least some of them aid in defense of the host from super-infecting related or unrelated phages, via restriction, exclusion, toxin/anti-toxin systems, abortive infection systems, and others; the mechanism(s) that contribute to this extensive localized genetic diversity is unclear.

The right arm of the flexible-tailed phage genomes is replete with small genes (~30–500 aa) of unknown function; as well as larger genes for which functions can be identified; those code for proteins involved in DNA replication, recombination, and nucleotide modification and processing. The smaller genes are characteristic of phage genomes in general, their role in the biology of the phage is unclear, nor are they similar to other sequenced phage genes available in GenBank. These genes of unknown function tend to be smaller than their counterparts to which a function can be assigned, likely both due to the lack of similar sequences of known function being present in the databases, but also due to the limitations of search algorithms in matching smaller sequences with statistically relevant specificity.

Transcriptomic and proteomic studies indicate that these small genes are expressed early during lytic infection, and in at least a few cases, are involved in the defense of the host cell against super-infecting phages – either self or unrelated. A putative role in host defense is further supported through whole genome essentiality studies performed – most of these small genes can be deleted from the genome with no effect on the viability of the progeny under laboratory monoculture conditions. This would make sense if these smaller genes are used to protect the host from further infection of other phages.

Mosaicism in the Myoviridae

The larger comparative genomic studies of the Myoviridae have primarily focused on the on the T4-like phages in Gram negative hosts such as *E. coli* and the marine Cyanobacteria *Synechococcus* and *Prochlorococcus*; indeed, while myoviridae of the Actinobacteria have been isolated, they do not exhibit the large complicated tails of the T4-like phages, and the two types of phage share no genes in common. The genomes of the T4-like phages generally are between 150 kb and 250 kb; they share some gene content in the form of a set of 20 or so “core” genes, present in all of these phages; core genes in this case being defined by functional analogy and protein sequence similarity. The majority of these shared genes are homologs of the structural genes of T4; T4 virions have a complicated structure and elaborate, multi-protein contractile tail designed to deliver the phage DNA by injection through the cell membrane and wall. To date, no temperate phages with a T4-like morphology have been isolated; all are lytic phages. Like the Siphoviridae, the overall gene order of the core genes within the Myoviridae is conserved; and indeed, the order from terminase through major capsid and neck proteins is identical to those of the Siphoviridae. The mosaicism of phage genomes is evident within the insertions of smaller genes of unknown functions between the structural proteins similar to the larger genomes of the Siphoviridae, the overall synteny of the structural proteins is maintained in these larger phages.

Mosaicism in the Podoviridae

The taxonomic classification of Podoviridae, or short-tailed phages, comprises at least two large unrelated groups; the short-tailed phages that are similar to the *Salmonella* phage P22 are more related to the lambdoid phages of *E. coli* such that the melted strands of the genomes can anneal and form heteroduplexes as demonstrated by Campbell (1994), than these phages are to other short-tailed phages. The larger comparative studies performed on Podoviridae have primarily included the phages related to *E. coli* phage T7, including phages of the Enterobacteria and phages of the marine cyanobacteria. These phages share little nucleotide or protein sequence similarity, but their genome size of approximately 40 kb, genome architecture, and functional gene content are highly conserved. The synteny of these genomes is evident in the comparative studies, with an RNA polymerase gene near the left end, followed by genes involved host takeover and in DNA replication, with the structural genes occupying the end of the right arm. Here there is a slight permutation from the gene order in the Siphoviridae; as the T7-like phage structural genes begin with the

portal gene, followed by the head, and tail genes, and end with the terminase. The smaller genes of unknown function show the most variety in terms of gene content across genomes, with the larger structural genes showing more conservation. Interestingly, some of these genomes include genes related to integrases found in temperate phages, but do not include identifiable homologs of the remainder of the machinery required for stable integration.

Clusters and Superclusters: Large Scale Comparative Genome Analysis

The mosaic nature of phage genes and genomes and the lack of a single gene present in all phages has made defining the boundaries of their relatedness a difficult task. A number of classification schemes have been used to group -related phages together; including morphology and host range. As more phage genomes were sequenced through the 2000s and 2010s, the more it became clear that these earliest metrics for classification were not sufficient; *Salmonella* phage P22 and *E. coli* phage lambda being the only two earliest examples.

The larger scale comparative analyses of complete genome sequences of phages infecting specific bacterial genera published in the past decade have upheld the earliest observations of genetic mosaicism across the tailed phages. Phages isolated from a multitude of hosts share genome architectures and functional units while exhibiting little or no nucleotide or protein sequence similarity; and many of the predicted protein encoding genes are small, only 300 bp or so on average, diverse, located in equivalent areas of the genomes, and do not have identifiable functions. The ubiquitous mosaicism and vast diversity of gene sequences has confounded traditional taxonomy based on vertical descent of genes; however, attempts at grouping phages by shared nucleotide sequences or by shared proteomes – also called shared gene content – have proved useful in identifying groups of related phage that share similar biological traits. Phages with similar gene content are assigned to the same “cluster”, however, these boundaries may still be fuzzy, in that phage A may share 35% of its genes with phage B, and phage B may share 35% of its genes with phage C; all three would be assigned to the same cluster even if phages A and C do not share 35% of their genes. The results of this type of cluster building is that given enough members, there may no longer be any single protein that is present in all cluster members; this is seen in the Cluster A of the Actinobacteria. These phages are temperate Siphoviridae with approximately 600 isolates with complete genome sequences listed on website provided in “Relevant Website section”, the Actinobacteriophage database. The most recent comparisons of phage gene content suggests that phages with similar genome architecture and sharing 35% or more protein sequences from across the genome, when shared proteins are measured through pham membership as determined by the program Phamerator, can be used to define cluster membership.

An analysis of Entereobacteriophages suggests the use of the term “supercluster”; these would include phages that share genome architecture, but few or no protein sequences across the group. The phages of the superclusters show diversity of host range across multiple genera; and provide evidence for the model of gene movement throughout the global population of phages proposed by Jacobs-Sera *et al.* (2012), in which different phage types exhibit different but overlapping host preferences (the “stepping stone” model). Recombination events between these co-infecting phages allows all phages access, albeit at different rates, to the continuum of diversity within global phage genetic space.

Different Phage Clusters Acquire New Genes at Different Rates

Comparative genomic analysis between and within phage clusters demonstrated that the rates of gene exchange and mosaicism were not equivalent between different groups of phages. With more than 3000 sequenced phages isolated on hosts from across the domain of bacteria, patterns in gene exchange and gene flow became evident. By examining the gene content and nucleotide sequence similarity of over 2000 phages in direct pairwise comparisons, Mavrich and Hatfull demonstrated that different phage clusters exchange genes at different rates; and moreover, that only temperate phages exhibit “high gene flux” – in which parts of their genomes are relatively identical in terms of gene content and nucleotide sequence (frequently, this corresponds to the left arm of the genome containing the structural proteins) – while the remainder of the genomes shares little to no genome sequence similarity or gene content. High-gene flux phages are more likely to swap entire genes than accumulate nucleotide changes within shared genes. This type of pairwise comparison is in direct contrast to the phages that exhibit “low gene flux”; and in these phages, changes between genomes are spread out evenly across the genome, and nucleotide changes within shared genes occur at about the same rate that entire genes are swapped between genes. To date, all lytic phages and some groups of temperate phages demonstrate low gene flux. These two different modes account for the seemingly irreconcilable observations of discreet phage populations observed within large lytic marine Cyanophages – these are low-gene flux phages with many shared genes, for which individual rates of nucleotide substitutions can be counted; while some groups of the temperate Actinobacteriophages within the high-flux mode share structural genes and little else. It is unclear as to the mechanism through which these phages mediate high gene flux.

Mosaicism, Hybrids, and Single Gene Surveys

Today’s sequencing technologies rely on shearing DNA into small, manageable fragments (100–1000 bp, depending on the sequencing technology used) prior to sequencing, followed by post-sequencing computer assembly of the small pieces into a

complete full-length genome. For purified DNA from phage isolates, assembly is trivial, however, for DNA sequences extracted from complex environmental samples (also called the metagenome of the sample) the mosaicism, vast numbers, and genetic diversity of the phage genomes makes assembly difficult. Nor is it easy to identify phage sequences recovered from metagenomic samples as there are comparatively few full genome phage sequences available for alignments. Some environmental survey studies use amplification of genes such as those encoding phage portal proteins, major capsid proteins, integrases, or DNA polymerase genes, and these are of some utility in determining the presence and diversity of phages containing those particular genes. While the majority of complete phage genome sequences support that single gene survey analyses may represent individual phage types, some exceptions have been discovered and are worth mentioning. First, a number of phage genomes of the Siphoviridae and Podoviridae from diverse hosts such as *Gordonia* and the marine cyanobacteria contain integrases without any other lysogenic components; nor have efforts at isolating lysogens from infections of these phages been successful. In these cases, the “integrase” genes may be merely homologous recombinases that facilitate the gene flow between these phage types and the host or co-infecting phages. Second, structural hybrids have recently been identified between the *Gordonia* and *Mycobacterium* phages (including the three shown in Fig. 1); the bottom two phages exhibit prolate capsids and the top has an isometric head. A similar relationship exists between the phages depicted in the figure, which illustrates a number of properties discussed in this article; including mosaicism, synteny, and conservation of genome architecture; these are not the only examples of structural hybrids, the marine phages of *Pseudoalteromonas* include a Myo/Sipho hybrid – in this case, the contractile-tailed phage is similar to the smaller less complex phage Mu rather than the larger complicated T4.

The rate and formation of hybrids is dependent on the size, type, and locations of functionally equivalent genes. The ratio of genome overall length to that occupied by essential genes directly impacts the amount of flexibility a phage genome has to acquire new genes without losing viability. As capsid sizes increase, phages have room to acquire new genes, but these new genes may be in the form of insertions between essential genes. As essential genes are moved farther apart from each other on the genome, the less likely it is that a non-homologous recombination event could accommodate the formation of a structural hybrid – thus it is unlikely that a lambda-T4 hybrid could even be recovered. It is also unlikely that a phage with a larger capsid size could downsize once enough new genes have been acquired; as truncation of the genome sequence may then include essential genes.

Additional genome sequencing of phages from a wider variety of phages may reveal more insights into the gene flow within the phage population.

Glossary

Bacteriophage-phage Virus of bacteria.

Diversity The number of species, their taxonomies, and their abundance in an ecological community. Generally represented by a diversity index, which is a quantitative measure of both, the richness and evenness of a community (e.g., Shannon Diversity Index).

Dysbiosis Microbial system imbalance within body. Dysbiosis is the disruption of a microbiota's commensal and mutualistic capacity. Dysbiosis is not a requisite criterion in health or disease though it is implicated in the etiology, persistence and progression of many diseases.

Eubiosis The healthy state of the human microbiome communities.

Fecal microbial transplantation or transplant (FMT) Transplantation of feces from a healthy individual donor to the gut of a recipient individual suffering a disease in order to restore a healthy microbiota.

Gnotobiotic mice Germ-free mice (devoid of microbes) that are colonized with exogenous microorganisms in order to study the effect of the microorganism on the host.

Human microbiome The human body in total as a conglomeration of human cells and microorganisms (the microbiota). The phage component is in turn referred to as the human phageome.

Lysogenic or temperate phage A phage that has the ability to integrate its DNA into the host chromosome where it is passively replicated with the bacterial chromosome.

Lytic phage A phage that upon injection of its DNA into its susceptible host cell replicates its genome, produces structural proteins and ultimately lyses the cell to release its progeny virions.

Metagenomics Study of DNA isolated directly from complex biological samples. DNA is isolated and deep-sequenced generating sequence reads that are assembled with bioinformatic programs to render an ensemble of DNA sequences from all the organisms present in the microbial community under study. Within this context, viruses can be purified and sequenced separately, rendering a viral metagenome containing sequences from viral entities. In contrast, cellular metagenomes will contain both cellular and viral sequences.

Phage therapy Use of specific bacteriophage or phage cocktails to treat bacterial infections.

Prophage reservoir All the prophages encoded in bacterial members of the gut microbial community.

Prophage A bacteriophage genome integrated in the bacterial host genome.

Introduction

Humans exist in homeostasis with a considerable diversity of microbial life, ranging from bacteria and their viruses-termed bacteriophages (phages), to eukaryotic viruses, archaea, protozoa, and fungi. Together these organisms comprise the human microbiome. Within this community, bacteria are the most abundant cell type and bacteriophages are the most abundant virus type. The composition of the human microbiome varies between individuals and body site, diet, geography and health status. Disease states can correlate with deviations in microbiome structure, termed dysbiosis, with respect to that of the healthy state. The causes of dysbiosis are a central focus of microbiome research.

Bacteriophages are a key ecological determinant affecting the dynamics and function of bacterial communities. Their role in shaping human bacterial communities, and ultimately in human health and disease, remains a key question. The study of phage-bacteria-human relationships spans the paradigms of health and disease, with phages being agents of both. Individual phages have been extensively studied as secondary agents of human disease, often conferring pathogenic traits to commensal bacteria. In other microbial systems bacteriophages are known to strongly influence the dynamics and function of their bacterial host communities. It is assumed therefore, that microbial viruses are partially responsible for the human microbiome's capacity to modulate host phenotype and cause, enhance or ameliorate disease. This assumption is underpinned by evidence that viral fractions of the microbiota alone can generate systemic changes in health. Phages can potentially influence the human host through predation of human pathobionts, and through direct interaction with the human immune system among other modes.

The human phageome has been studied at both a multi-trophic systems level, as well as at the individual virus level. To this end, a number of tools have been developed to further our understanding of the features and dynamics of bacteriophages within the human microbiome. Quantification of purified phages using fluorescent DNA intercalating dyes and direct visualization by electron microscopy have allowed for the estimation of phage densities and provided information on the virion morphologies of those communities. Advances in 'omics' technologies (primarily genomics) and bioinformatic tools have permitted in-depth

¹The authors contributed equally to this work.

Fig. 1 Human microbiome phages across several body sites.

characterization of human phages at the community level. Specifically, next generation sequencing technologies (NGS) have provided a more complete understanding of phage diversity and community structure associated with different human developmental and health states. Mouse models, both gnotobiotic mice which can replicate specific bacteria-phage dynamics or community dynamics, as well as conventional mouse disease models which replicate disease-associated changes in humans, have been used to investigate the overall phageome composition and its influence on host health. The increase of human fecal microbial transplantation (FMT) to treat several gut associated diseases has provided new opportunities to study human gut phage temporal ecology. *Ex-vivo* and *in-vitro* models have been employed to decipher the same dynamics as the other systems mentioned as well as mechanisms of spatial localization for certain phage. This combination of research tools has provided invaluable insights into the role of phages in health and disease.

This article examines phages in human microbiomes from three different perspectives: the distribution and composition of the human phageome across individuals and body sites, the dynamics of the phage community within specific body sites, and the applications of bacteriophages for human health. Each of these aspects exists at the intersection of multiple dimensions including time, intra- and inter-individual variation, health and disease.

Human Phageome Distribution and Composition

Bacteria and their viruses populate nearly all external features of the body (Fig. 1). These sites range from highly habitable to depauperate. Like the bacteriome (the collection of all bacteria present in a given microbiome), the composition of human-associated phage communities is significantly affected by body site. Micro-habitats of the skin, for instance, are populated by fairly simple resident microbial and viral communities. These communities are generally composed of *Staphylococcus* and *Streptococcus* phage, such as *Staphylococcus capitis* phage STB20, being the dominant prokaryotic phage. Itinerant microbes pass through these habitats frequently from other environments. In contrast, the vaginal environment hosts a more complex and overall more stable microbial community that is usually dominated by *Lactobacillus* species and lactobacillus phages. Gastrointestinal (GI) tract communities are dominated by *Streptococcus* and *Prevotella* species, and presumably their viruses in the oral cavity, and members of the Bacteroidetes, Firmicutes, Proteobacteria and Actinobacteria phyla and their viruses in the gut. The majority of microbes make their home in the GI tract, which is one of the main immune organs in the human body. The GI tract is therefore the largest interface between microbes and human immune cells; and the largest microbe-microbe interface, making it a fruitful area for microbiome research. It encompasses the majority of studies carried out on the human phageome.

Beyond external surface habitats, phages are also found within the body. Active phage particles have been isolated from blood and organs. The process of phage transcytosis, in which phage particles passively move across epithelial layers, likely contributes to their internal presence, although active transport systems may also exist. Using tissue culture models of gastrointestinal epithelium, it has been estimated that approximately 31 billion bacteriophage particles cross the gut epithelium into the body every day. The

presence of internal active phage particles may provide a cooperative immune function for the human host, although its exact implications on both the human host and microbial dynamics have yet to be determined.

Along the length of the GI tract there is significant variation in the abundance of bacteria and viruses. Microbial cell densities are high in the oral cavity ($\sim 10^8$ /ml of saliva) and decline towards the stomach. Beyond the stomach, cell densities increase progressively through the small intestine and number in excess of 10^{11} cells per cm^3 in the colon. Phages reside in the lumen or associated with mucosal membranes (e.g., gums, gut mucus) in similarly high numbers to their bacterial hosts. It has been estimated that between 10^9 and 10^{11} virus particles per cm^3 are present in the lumen compared to 10^8 – 10^{10} virus particles per cm^3 in the mucosa. However, accurate measures of phage densities across both radial and longitudinal axes are difficult to determine. The ratio of phages to bacteria varies between 1:1 and 1:10, which is significantly lower than the phage to bacteria ratios observed in other environments, like the ocean, where phages commonly outnumber bacterial hosts. The differences in phage to bacteria ratios observed between different environments may be linked to cell density, with high cell density favoring lower phage to bacteria ratios. Understanding the spatial and temporal dynamics of phage-bacteria associations at a finer scale will provide critical information on role of phages within the GI ecosystem.

Within an individual, tens to hundreds of phage species can be found at any given time in either the oral cavity, the small intestine or the colon. The highest phage load is found in the colon, followed by the oral cavity and small intestine, however, the oral cavity hosts the most diverse phage community. The majority of phages metagenomic surveys have been carried out in the oral cavity and in stool samples, which serve as a proxy to study the colon microbiome. In both environments, the phage community is relatively novel since >60% of the phage DNA sequences found in these studies are not represented in cultured phage isolates. However, the overall phage diversity is lower than what is observed in other microbial environments. The GI tract phageome is characterized by a lower species richness and a very uneven phage distribution, with a minority of phage types comprising a majority of the total phage particles. Without perturbation, the gut phageome can remain surprisingly consistent within an individual over the course of years. When comparing the phage community among different individuals, the gut phage community is specific to each individual. In contrast, the oral cavity phageome shows more temporal variation within an individual.

Despite being characterized by an individualized phageome, some GI tract phages are globally distributed (Fig. 2). For example, the gut crAss-like phage is distributed broadly across the human population. CrAss phage has been found in most individuals, and can make up nearly 90% of the community in some people. How and when these phages are acquired is an open question. Through environmental exposures such as common interactions and cohabitation, individuals are constantly exposed to phages from other people and the environment. Most of these viruses do not colonize at detectable levels but a small proportion can establish residency. Consequently, gut and oral phage communities tend to be more similar between individuals within a same household and between relatives (e.g., siblings, mother and offspring). A subset of phages is commonly found in healthy people and less so in diseased individuals (e.g., patients with irritable bowel disease-IBD), which contributes to the notion of phages being agents of health in addition to their known roles in acute disease.

The dsDNA phages of the Caudovirales order and ssDNA Microviridae phages are the most commonly observed phage types in the gut. Both viral metagenomics and direct observation by electron microscopy indicate the dominance of these two taxonomic groups. However, it is important to note that over 60% of the genomic sequences obtained from human gut phages do not share sequence homology with known viruses and therefore cannot be classified. Of the classifiable phages, Microviridae generally

Fig. 2 Factors affecting composition and global distribution of GI tract bacteriophage. The individual composition of the gut phage community is impacted by a complex array of factors. Overall, healthy individuals harbor a mixture of individual-specific phages and a smaller subset of phages globally distributed and commonly found in healthy individuals.

Fig. 3 The adult human gut phage community in health and disease. Human gut phages found in stool samples are a mixture of lytic phages and activated prophages from the prophage reservoir. During certain diseases, the phage community composition is changed. An increase in prophage activation, activation of a different subset of prophage, or an increase of lytic phage potentially contributes to these changes. A balance between lytic and temperate prophage, and an adequate regulation of the prophage reservoir is important to maintain health. Reprinted from Manrique, P., Dills, M., Young, M.J., 2017. The human gut phage community and its implications for health and disease. *Viruses* 9.

dominate in healthy gut communities. An increased abundance of Caudovirales phages has been associated with certain diseases. For instance, in individuals suffering from IBD, the classifiable Microviridae to Caudovirales ratio is significantly decreased. Other prevalent classified gut phages include the 936 group of lactococcal phages, N4, I3, Mu, Hp1, P2, PhiCD119-like viruses. Most RNA human associated viruses are eukaryotic, with only a limited number of RNA phages detected within human fecal matter. It is important to note that the majority of studies characterizing the phage community are carried out using stool samples due to the difficulty and scarcity of access to intestinal tissue for research. In humans, stool phage content significantly resembles that of the colon, providing a good approximation to study human gut phages. In mice, where access to intestinal tissue is easier, differences in both the phage community composition and dynamics between the colon and the small intestine have been identified. However, information about the fine scale spatial distribution of phages within the human gut ecosystem is scarce and should be addressed when possible.

At least 50% of human-associated bacteriophage particles isolated from stool samples can be characterized as prophages derived from lysogenized bacterial strains. The majority of identified prophage sequences in stool samples are found as integrated prophages in Firmicutes, Bacteroidetes and Proteobacteria bacterial species, which comprise the main bacterial phyla found in the gut. Lambda-like and phi80-like coliphages are found in the majority of healthy individuals. Within the Firmicutes phyla, an in-depth characterization of prophages of *Faecalibacterium prausnitzii*, a species highly associated with human health has been carried out, showing that the majority (>70%) of these genomes contain at least one prophage. Bacteroidales-like temperate phages are highly prevalent in cellular metagenomes of healthy adult individuals, but are nonetheless underrepresented in viral metagenomes from stool samples. Some of these prophages are classified as Microvirus, a genus from the Microviridae viral family. Previously, this viral genus was considered to be strictly lytic. This type of prophage is shared among different individuals and can be used to group healthy individuals based on the types of prophages they harbor (i.e., viral enterotypes). However, most gut isolated Bacteroides phages including crAss-like phages, do not have lysogenic capabilities and are thought to be maintained in the gut through persistent infections. The oral cavity and vagina are also rich in temperate phages, with Firmicutes prophages being the most abundant in the oral environment and Lactobacillus phages in the vagina.

The regulation of prophage activation is likely a key determinant of microbiome 'health' with important consequences for human health (Fig. 3). Approximately 70% of gut bacteria contain at least one prophage in their genome. At any given time, a subset of these prophages are induced, producing viral particles which make up a major part of the active phage community. The totality of microbiome prophages is known collectively as the microbiome prophage reservoir. Using murine models, it has been demonstrated that activated temperate phages account for a large fraction of the viral particles found in fecal samples, creating an active viral pool. It is thought that external changes, such as diet or antibiotic treatment, significantly affect the type of prophage that enter the lytic cycle causing a shift in the active temperate bacteriophage community. A model known as the "community shuffling model" proposes that changes in the bacterial community associated with certain diseases arise partly from changes in the prophage activation profile. For instance, individuals suffering from IBD, in which *F. prausnitzii* abundance is significantly lower compared to healthy individuals, present a greater abundance of active *F. prausnitzii* prophages in their stool sample. This, together with changes in the ratio of lytic and temperate phages observed in certain diseases has led to the hypothesis that a balanced prophage activation is necessary to maintain health. A more extensive characterization of human associated temperate phages across different body sites, time, and health state is needed to test this hypothesis and understand their ecological role in the human microbiome.

Both phage and bacterial communities fluctuate through time and display certain trends correlating to the stages of human development. Gut phage diversity at birth is extremely low, but increases significantly within days after birth. The composition of infant gut phageomes is influenced by the type of birth (natural vs cesarean) and the newborn food intake (breast fed vs formula), as most of the prophages are transferred from the mother to the child inside bacterial lysogens. The most abundant phages in newborns are those infecting *Lactobacillus* and *Bifidobacterium* sp. As the infant ages, prophages become active and predate on their host species contributing to the microbial dynamics that take place within the gut of the newborn. Soon after birth, several factors such as time, diet and phage predation alter the microbial community composition and structure. A shift to Bacteroides and

Fig. 4 Phage microbiome trophic interactions.

Firmicutes phages occurs corresponding with a rise of *Bacteroides* and Firmicutes hosts within the bacterial community. The proportion of lytic to temperate phages in the gut is altered as well, with lytic phages predominating in early childhood. As both the bacterial and phage communities gain complexity, this balance switches to favor lysogenic phages and their lysogenized hosts. Much of the phageome temporal stability seen in adulthood is hypothesized to be the manifestation of a predominantly temperate phage community, as integrated or episomal prophages (the prophage reservoir) are able to persist in the gut by sheltering within select bacteria.

Diet and drugs can exert strong selective forces on the gut phageome (Fig. 4). By modulating the nutrient landscape, dietary elements can promote certain bacterial assembly patterns which in turn alter the composition of the phage community. Antagonistic compounds derived from the diet or consumed as medication can also influence gut phage dynamics through depletion of bacterial hosts and activation of prophages. Changes due to dietary intervention are generally reversed upon return to a conventional diet, however, in some cases, the phage community fails to return to its prior state. During and after antibiotic treatment, bacterial diversity is significantly decreased, whereas viral richness is not significantly affected, in all likelihood due to an increase in antibiotic-induced activated prophages. However, antibiotics do cause a shift in the overall phage community membership. It is hypothesized that this apparent greater resilience in the phage community potentially contributes to the ability of the bacterial community to return to equilibrium after disruptions, including disease.

Both acute and systemic diseases often correlate with bacterial and phage dysbiosis in the microbiome (Fig. 3). General changes in phage number, phage diversity and the prevalence of certain phage types can be indicative of unhealthy states. For example, phage taxonomies commonly associated with healthy individuals are underrepresented in patients with IBD. IBD patients with different disease type (colitis vs Crohn's disease) harbor different phage assemblies, generally characterized by an increase in classifiable Caudovirales phages, an increase in strictly lytic phages, a decrease in Clostridiales phages, and an increase in phages associated with pathobiont hosts. The number of detectable phage particles can also change. Mucosa-associated phages are more abundant in individuals with IBD and leukemic disease patients. These features may be attributed to changes in prophage activation profile (community shuffling model) or an increase in lytic bacteriophages. Consistent with this model, a shift from a temperate lactobacillus phage-enriched environment to a more lytic-enriched one in the vaginal microbiome has been associated with bacterial vaginosis. Phage communities are significantly altered in patients suffering from a variety of diseases, ranging from periodontal diseases to bacterial vaginosis, cystic fibrosis, type 2 diabetes, IBD and malnutrition. These changes result in differences in phage diversity; impacting the bacterial community with potential consequences for human health. Phages can also act as vectors of pathogenicity, like cholera toxin CTX ϕ phage and shiga toxin encoding Stx phages. Though many are transient to humans and exist within their host bacteria causing acute disease, a spectrum of these phages can infiltrate the human microbiome. At the cost of increased predation, many pathobionts are highly permissive to temperate phages which can provide advantageous genetic factors. These organisms and their associated phages can exist in a commensal or infectious capacity which dictates their broader distribution across the human population as members of the microbiome.

Dynamics and Implications of the Human Phage Community

Phages engage in a full spectrum of symbiotic interactions with bacteria, from mutualism to parasitism, each contributing to significantly different outcomes in their bacterial host population. Virus predation drives the evolution of both phage and host, likely

through a constant arms-race directional selection, in which selection and propagation of bacterial mutants resistant to phage predation is followed by the emergence of virus mutants that are able to infect the newly evolved strains. Lysogeny offers an alternative host-virus association. Upon integration of a phage genome into the bacterial chromosome, an altered symbiosis is created. The prophage fitness burden can be compensated through prophage-encoded advantages such as protection from superinfection, lysis of competing bacteria, or utilization of advantageous prophage-encoded genes such as antibiotic resistance genes or polymorphic toxins. In complex microbial environments, like the oceans, phages have been shown to have predominantly lysogenic cycles under unfavorable conditions (e.g., low nutrient availability, low host densities). However, increasing host densities (e.g., the gut ecosystem) might also favor the strategy of lysogeny as proposed in the Piggy Back the Winner model (PbW). Some phages may remain in a state between lysogeny and lytic replication known as pseudolysogeny, in which the viral genome remains as an extrachromosomal unit, without being degraded, until it is either actively replicated or integrated into the host genome.

Host-phage dynamics have been primarily explored in the intestinal tract and the oral cavity. Within these microbiomes, the human developmental stage and specific tissue site (e.g., saliva compared to sub- and supragingival areas in the oral cavity or small intestine compared to cecum and colon in the GI tract) are some of the key factors dictating host-phage dynamics. In the gut microbiome of newborns, rapid colonization with the mother's microbiome leads to density dependent (Lotka–Volterra) host-phage dynamics that fade with time as the community reaches an equilibrium and becomes enriched with lysogenic phages. In adulthood, host-phage dynamics change considerably within different sections of the GI tract. For instance, lytic dynamics are more common in the oral cavity than in the gut. Analysis of phage-host abundance and genome evolution in murine models has shown that within the intestinal tract there is reduced directional selection, evident by a decrease in the appearance rate of phage-resistant bacterial mutants. This may be due to epigenetic variability of bacterial host populations in response to different chemical micro-environments within the gut allowing the bacteria to evade phage predation without necessarily modifying their genomes. These observations are our first indications of the mechanisms driving the balance between lysis and lysogeny, and the prevalence and role of pseudolysogeny and their contributions to host-phage dynamics.

The effects of bacteriophages in the gut are beginning to be unraveled primarily using a combination of animal models and NGS technology. Animal models in which germ-free mice are colonized with two bacterial strains— one containing a prophage and a second strain susceptible to the prophage, or with a bacterial consortium representative of the human microbiome, have been used to elucidate the role of GI phages. Within this context, it has been shown that prophage induction rate is significantly higher in the gut than rates observed *in vitro*. The ‘cost’ of prophage induction (lysis) in a subset of the bacterial population encoding the prophage, may be compensated by the ability of the temperate phage particle (activated prophage) to kill competitor strains. It is also possible to establish a more complex microbial community that is more representative of the gut ecosystem by colonizing either germ free mice or *in vitro* chemostat-based bioreactors with human stool samples. This, together with conventional mouse models, has shown that the phage fraction influences the bacterial community structure and that it likely contributes to its resilience after disruptive events such as antibiotic treatment. Recently, more specialized models such as ‘gut on a chip’ are becoming important tools to investigate how the human epithelium and mucosal surfaces can impact bacterial-phage interactions with important consequences to the human host.

The GI tract provides extensive mucosal surfaces onto which some bacteriophages can adhere in high localized densities, altering site-specific phage-bacteria ratios (Fig. 5). In the gut, phage adherence to mucosal surfaces has been described by the bacteriophage adherence to mucus (BAM) model. Briefly outlined, the BAM model proposes that the binding of certain bacteriophages to mucus glycoproteins through immunoglobulin-like domains found on their capsids alters their diffusive properties, increasing the density of phages in outer mucosal layers where they are more likely to encounter susceptible hosts. This mechanism not only allows for the increased success of the adherent phages, but it also confers potential immunity to bacterial invasion of the gut epithelium. The BAM model may operate in other mucosal surfaces of the body as well, such as gums, where bacteriophages can be found bound to the oral mucous membranes in extremely high concentrations compared to their bacterial counterparts (35:1 ratio).

A model that integrates both BAM-based immunity and lysogeny-driven PbW dynamics proposes that bacteriophages can provide a level of protection against bacterial invasion of the epithelium (Fig. 5). In this model, lysogeny, which is prevalent in the lumen and at the surface of the mucosal layer, is thought to confer competitive advantages to commensal bacteria in the highly colonized areas of the gut through symbiotic interaction between the lysogen and the prophage. Simultaneously, lytic phage predation, enhanced in the dense mucus layers, is likely involved in eliminating potential pathogens. Similar dynamics are seen in the oral cavity. Regardless of whether phage infection is of lytic or lysogenic nature, phages can alter the metabolism of their host cell in order to promote their successful replication, influencing the overall functional profile of their microbial communities.

To better understand phage-bacteria dynamics, it is important to determine the host range of the phageome. Bioinformatic analysis of metagenomic datasets suggests that some members of the human phageome may have a broader host range than previously appreciated. Through mechanisms that increase phage genomic diversity, such as single nucleotide mutations and rearrangements of tail fiber genes, gut microbiome phages can alter their host specificity allowing persistence through time. These results have been validated with mouse models and in culture.

At the community level, phages likely stabilize human microbiomes and provide a degree of resistance to external changes and colonization. For instance, the gut microbiota is deeply affected by antibiotic treatment, after which a new, but similar, microbial “steady-state” is restored. Antibiotic pressure leads to an increase of phages that encode antibiotic resistance genes, potentially contributing to the resilience of the bacterial community, which is a hallmark of healthy microbiomes. These observations suggest that phages could contribute to re-establishing a healthy symbiosis altered during changes caused by disease. The bacterial

Fig. 5 Phage-bacteria and phage-human interactions within the intestinal tract.

Fig. 6 Role and applications of human associated bacteriophages.

community established after fecal microbial transplant (FMT), is likely influenced by the original phage community. However, it is important to keep in mind that phages may also augment disease development by enhancing dysbiosis in the microbiome.

The use of whole microbial community transplants (e.g., FMT) as an effective treatment of gut-microbiome associated diseases, provides an ideal scenario to study both the influence of bacteriophages on the resilience of the gut microbiome and the capability of bacteriophages to modulate changes in the microbial community structure. Based on the effectiveness of fecal microbial transplantation in treating *C. difficile* infection this practice has been implemented in the treatment of other diseases. The type of

eukaryotic viruses and bacteriophages hosted by a subject have been linked with treatment success, suggesting that both, the viruses that were already in the patient and the viruses which are able to establish after treatment, may affect the outcome of the procedure. Donor-patient compatibility is likely an important factor for phage transfer and treatment outcome.

Clinical Utility of Bacteriophages of the Human Microbiome

Since their discovery in the early 1900s, bacteriophages have been investigated as biotherapeutics to control bacterial infections for diverse applications, ranging from food safety to disease treatment in animals and humans (Fig. 6). It was proposed early on that phage therapy using cocktails of purified phages could eliminate bacterial infections. However, the emergence of commercial antibiotics in the late 1930s and the variability in phage treatment success limited the pursuit of phage therapy in Western medicine. The rise of antibiotic resistant human pathogens has rekindled interest in phage therapy. Phage therapy has been successfully used to eliminate topical (e.g., *Staphylococcus* sp. skin infections), internal or systemic infections (e.g., gut-derived sepsis due to *P. aeruginosa*, multi-drug resistant *E. coli* infection, and *C. difficile* infection), and successfully personalized as intravenous phage therapy for treating *Acinetobacter baumannii* septicemia.

Advancement of phage-based therapeutics will require a better understanding of the ecological forces that shape phage establishment and dynamics within human microbiomes. Elimination of specific pathogens within complex bacterial communities, such as the gut microbiome, is currently a challenge for phage therapy implementation. Important variables included phage host range, host range switching, and the control of the cell lysis process. Ideally, phage therapy could be used to eliminate specific pathogenic bacteria without disruption of the commensal bacterial community, mitigating the potential for secondary infections caused by off target antibiotic effects. If successful, phage therapy may provide a cheap and effective alternative to antibiotics.

From an ecological viewpoint, phages are crucial members of the human microbiota in both health and disease. Therefore, it is reasonable to consider that phages can be used not only to treat specific bacterial infections, but to return a dysbiotic bacterial community to eubiosis. Effective treatment of *C. difficile* infection, an opportunistic pathogen that is associated with a decrease in gut microbiome diversity, can be accomplished by application of fecal filtrates which are greatly enriched in bacteriophages. The use of complex mixtures of bacteriophages isolated from healthy individuals presents a potential therapeutic treatment of more complex human diseases associated with dysbiotic bacterial communities such as IBD, or non-gut related diseases, such as periodontitis or bacterial vaginosis. A long-term goal of phage therapy is to provide safe and effective phage cocktails to control the microbiome bacterial community structure and function by design.

Alongside their role as important biological agents that can modify microbial communities, phages may emerge as useful biomarkers of health and disease. Specific phage sequences may be identified that can separate individuals based on their health status. Phage-based biomarkers have been shown to be useful to determine healthy, at risk individuals and subjects more likely to respond to treatments involving modification of the gut microbial community.

Concluding Remarks

It is well established that human associated microbes are key factors contributing to human health and disease. There is increasing evidence that phages play a direct role in microbiome health and disease. However, our knowledge of bacteriophage communities in human microbiomes remains sparse. Advances in sequencing technologies, phage annotation, animal and in-vitro models, and clinical human trials are significantly contributing to our understanding of phage-bacteria-human interactions. The influence of phage particles inside of the human host also requires further research. Within the next decade, we foresee a significant advance in human phage biology, which will result in applications that improve human health and limit disease.

Glossary

λ Red system The generalized recombination system of bacteriophage λ , which infects *E. coli*. The Red system consists of a 5' $\rightarrow$ 3' dsDNA exonuclease, Exo, and a ssDNA annealing protein, Beta.

Bacteriophage A virus that infects bacteria.

***Escherichia coli* (*E. coli*)** A well-studied genetically tractable Gram-negative bacterium.

Exonuclease An enzyme that digests linear DNA from the ends. Exonucleases are classified according to their degradation properties.

Genetic engineering *In vitro* or *in vivo* manipulation of DNA segments to form new sequences.

Heteroduplex DNA A double-stranded DNA with the two strands derived from different molecules.

Homeologous DNA DNAs with partially but not completely identical nucleotide sequences.

Homologous DNA DNAs with identical or nearly identical nucleotide sequences.

Methyl-directed mismatch repair (MMR) A method that bacteria use for detecting and repairing mistakes created during synthesis of new DNA.

Oligonucleotide For the purposes of this article, a commercially synthesized piece of single-stranded DNA, generally ~ 70 nt long.

Prophage A bacteriophage chromosome integrated into the chromosome of its bacterial host, with most of the viral functions repressed by a phage-encoded repressor protein. An intact prophage can excise from the bacterial chromosome in response to an environmental stimulus and undergo lytic growth to make new viruses.

Rac prophage A defective *E. coli* prophage that contains the RecET system. Defective prophages are unable to excise and undergo a lytic cycle, but they still encode functional genes.

RecET The generalized recombination system of the Rec prophage. The RecET system consists of a 5' $\rightarrow$ 3' dsDNA exonuclease, RecE, and a single-stranded DNA annealing protein, RecT.

Recombinase For the purposes of this article, an enzyme that promotes pairing of two complementary single-strand DNAs.

Recombination The rearrangement of DNA sequence in a new order.

Recombineering *In vivo* genetic engineering with bacteriophage recombination functions.

Selection/countersélection A two-step procedure of genetic manipulation using two adjacent gene cassettes, one of which can be selected for, and the other selected against.

Single-strand annealing Pairing of two complementary single-strand DNAs.

Introduction

Over the past two decades, a phage-based genetic engineering technology in bacteria has emerged that allows any stretch of genomic DNA in a bacterial chromosome, or endogenous plasmid, to be easily altered in a precise manner. Many different genetic changes can be made, including gene knockouts, replacements, insertions, deletions, and point mutations. This technology, termed recombineering (for *in vivo* recombination-mediated genetic engineering) relies on the expression of bacteriophage-encoded homologous recombination functions in the absence of all the other phage functions. This article will first review studies of the phage λ Red recombination system and how it operates during a phage infection, followed by details of how two phage homologous recombination systems, Red from phage λ and RecET from the cryptic Rac prophage, have been utilized to create new genetic engineering tools. What makes the phage systems so practical for *in vivo* engineering is that short DNA homologies (~ 50 bp) are adequate for targeting, such that recombination substrates can be generated using PCRs of drug-resistant markers, with targeting homologies of these substrates incorporated into the PCR primers. Short DNA oligonucleotides can also serve as substrates for recombineering. Thus, allelic exchange substrates are easily generated for gene targeting of bacterial chromosomes, as well as eukaryotic DNA cloned into cosmids and bacterial artificial chromosomes (BACs). This technology has impacted an array of diverse fields such as the study of bacterial pathogenesis, metabolic engineering, synthetic biology, and mouse knockout technologies.

Bacteriophage

Since Twort and d'Herelle first discovered the existence of bacterial viruses in the early 1900s, these organisms have been under intensive study. Bacterial viruses are commonly known as bacteriophages (bacteria eaters) or phage. By the 1930s, they were employed as therapeutic interventions for diseases such as cholera and dysentery, though the details of the reported successes of

these treatments were not properly documented. The advent of antibiotics in the 1940s during WWII, together with the lack of interest by medical professionals in the West, led to only limited use of phage therapy as a modern way to combat bacterial infections. Phage therapy was mostly studied and developed at the Eliava Institute in the Republic of Georgia from the 1930s onward, where to this day, phage formulations are still used to treat bacterial infections of the skin and gut, and other infections that have proved refractory to antibiotic treatments.

By the 1940s, however, bacteriophages moved to center stage in a different venue, as a major tool that led to the development of modern-day molecular biology. The physicist Max Delbrück founded the phage group with a goal of characterizing these invisible creatures to better understand the basis of life. As the new field of molecular biology grew, the phages and their bacterial hosts served as primary model organisms. Early concepts of molecular biology were established by members of this group using bacteriophage and their hosts, which included the discovery of genetic mutations in bacteria, the structure of DNA and how it replicated, the triplet nature of the genetic code, and the capacity of DNA to repair itself, including mechanisms of general DNA homologous recombination.

The phage group studied various bacteriophages, primarily the T-even lytic phages. In 1953, Esther Lederberg reported the isolation of a new phage, λ , as a prophage resident of *Escherichia coli* that could be induced from the host cell to propagate lytically. λ is thus a temperate phage and maintains two life-styles: it is able to integrate its 48.5 kb double-stranded DNA (dsDNA) chromosome into that of its *E. coli* host, allowing passive replication of the phage DNA along with that of the bacterium. In this prophage state, the viral lytic functions are repressed until the virus is triggered to undergo lytic growth and make more phage particles, a process that results in lysis of the host cell by phage encoded enzymes. During the lytic growth cycle phage chromosomes are both replicating and recombining with each other, in a process to generate long concatemeric DNA species, which are the precursors for packaging phage chromosomes into newly formed phage heads. It was this system that led early investigators to use phage λ as a tool to study DNA homologous recombination, as one could easily infect bacteria with two mutant forms of the phage, allow them to recombine with one another during a single infection cycle, then determine the numbers of wild type progeny that were generated following lysis of the bacterial cell. It offered hope to determine, in a very simple system, the mechanisms of initiation and resolution of DNA homologous recombination intermediates.

Homologous Recombination Systems in *E. coli* and λ Phage

DNA homologous recombination is an important universal process in all forms of life. In simple terms, it is genetic exchange between identical or near identical DNA sequences. Its existence is required for lateral transfer of genetic material between bacteria, for the genetic variation generated during sexual reproduction, and for the repair of dsDNA breaks that occur either spontaneously, or because of the presence of DNA damaging agents. In essence, homologous recombination is the guardian of the genome, where mutations in genes encoding recombination functions can lead to the development of cancer (e.g., BRCA1) or to instability of chromosomal structures and numbers. One of the first species to be used in the laboratory to define the genetic requirements of homologous recombination, and subsequently its molecular mechanisms, was *E. coli*, and its infectious particle, phage λ .

E. coli has a homologous recombination system that is important for the incorporation of foreign DNA into the chromosome and for repair of damaged DNA. In 1962, A. John Clark and Ann Margulies isolated mutants of *E. coli* defective for recombination. These mutations were in a gene that became known as *recA*. The RecA protein plays a central role in almost all pathways of recombination in *E. coli*, by binding to single-stranded DNA (ssDNA) and promoting invasion of the RecA-ssDNA filaments into homologous dsDNA, the initiating event in almost all types of both prokaryotic and eukaryotic homologous recombination systems. Soon thereafter, other *E. coli* genes were discovered that also played roles in homologous recombination. These included the genes *recB*, *recC* and *recD*, whose products form a trimeric protein, RecBCD, which binds to the ends of dsDNA and digests both the 5' and 3' strands in a highly processive manner. RecBCD, also known as ExoV, is an *E. coli* dsDNA exonuclease complex capable of degrading linear intracellular dsDNA at a rate of 1000 bp/s. As this powerful exonuclease translocates along, it nicks both strands of dsDNA until encountering an 8 bp sequence called Chi (crossover hotspot initiator – 5' GCTGGTGG 3'). Recognition of the Chi site alters the enzymatic properties of RecBCD such that degradation of the 3'-ended DNA strand is suppressed. Further translocation of RecBCD past the Chi site allows continued production of a long ssDNA with a 3' end, which serves as a substrate for the RecA protein.

As noted above, it was recognized that λ phage was able to recombine its DNA in *E. coli*. The question arose if λ used the host RecA-RecBCD functions to recombine, or whether it possessed its own recombination system. An answer to this question came in 1967 when Brooks and Clark found that if the *E. coli recA* gene was inactivated, λ could still promote recombinant formation during phage infection. Thus, it was clear that the phage possessed a generalized recombination system that could work independently of the host RecA protein. Soon thereafter, mutants in λ were identified that disrupted this new phage recombination system. This system was called λ Red, named after the recombination-defective phenotype displayed by these mutants. It was shown genetically that these λ mutants formed two complementation groups, α and β . Biochemical studies later determined that the α gene encoded a dsDNA 5'-3' exonuclease (called Red α or λ Exo), and the β gene encoded a protein that stimulated annealing between two homologous ssDNA molecules (called Red β or λ Beta protein). A third λ gene, γ , affects recombination indirectly: the encoded protein (λ Gam) was found to inhibit RecBCD by binding to the dsDNA binding site of the enzyme, thus inhibiting RecBCD from binding to dsDNA ends. The Gam protein prevents RecBCD from interfering with λ Exo-Beta complex processing of dsDNA ends, thus indirectly stimulates Red-stimulated recombination. It is noteworthy that the λ phage recombination system is assisted by the Gam protein, which directly inhibits a major component of the *E. coli* recombination system (RecBCD). This turns

out to be a requirement, as the λ chromosome contains no Chi sites, and thus cannot efficiently utilize the host recombination system. Since it lacks Chi sites, the λ chromosome is susceptible to complete digestion by the dsDNA exonuclease activity of RecBCD unless the Gam protein is present.

Over a number of years, work from various laboratories contributed to the genetic and biochemical characterization of the λ Red system. Scientists in F.W. Stahl's laboratory at the University of Oregon, in the C. Radding lab at Yale Medical School, and in the laboratories of T. Poteete and K. Murphy at the University of Massachusetts Medical School were instrumental in defining the *in vivo* activities and biochemical properties of the Red system, as well as the phage P22 recombination system, and distinguishing them from contributions from the hosts. Two key concepts emerged from these studies: (1) In the absence of RecA, the λ Red system required DNA replication of the phage chromosomes to promote high levels of recombination. Many of these studies came from replication-blocked phage crosses, where λ Red recombination was highly dependent on RecA. This observation highlighted the direct link between the mechanisms of DNA replication and recombination for the Red system, a mechanistic coupling unique to the phage that does not occur in its *E. coli* host. (2) A key biochemical finding was that the *E. coli* RecA protein and λ Beta protein promoted different types of reactions with ssDNA. While a RecA-coated ssDNA filament was capable of finding homologous DNA in the context of the DNA duplex (*i.e.*, strand invasion), λ Beta protein bound to and accelerated the annealing of ssDNA to a complementary ssDNA species. The ssDNA substrate, in the case of Beta, was provided *in vivo* by the action of λ Exo when it initiated DNA degradation of a linear phage chromosome.

Biological Roles of the λ Red System

Role in DNA Replication

Enquist and Skalka observed that Red-mediated recombination is required for optimal levels of λ DNA replication. Both the rate of replication and the total amount of λ DNA generated are lower in *red* mutants. This defect is not rescued by RecA function, suggesting that at least partially non-overlapping functions exist for the phage and host generalized recombination systems. The DNA rolling-circle replication forms that predominate during the late stage of the phage replication cycle are likely to be substrates for Red recombination, since they contain dsDNA ends and active replication forks. It was later noted that rolling-circle tails are shorter in a *red* mutant background, suggesting that two replicating linear molecules may be recombined into a longer one by the Red system. The products of rolling-circle replication intermediates are multimers of λ chromosomes, termed concatemers. These concatemers are the DNA substrates utilized by the phage terminase enzyme for packaging individual chromosomes into protein capsids. Red is important in generating larger concatemers, thus making more packageable λ chromosomes. However, long concatemers can also persist in the population in the absence of Red, as long as the Gam protein is present. In this case, Gam, by binding to RecBCD, protects the dsDNA ends of rolling-circles, thus allowing these replication intermediates to form concatemeric DNA. While recombination is not absolutely required for the formation of packageable DNA, it stimulates this process.

Genetic Exchange Among Similar Phages – Generating Genetic Diversity

The lambdoid phages as a group share similar genomic organizations. The recombination, replication, and morphogenesis functions all share similar positions along the length of the chromosome when lambdoid phage genetic maps are compared. Although individual protein factors may differ structurally, and functions from one phage may fail to complement mutations in analogous genes of other lambdoid phages, complete functional modules, which may include several genes, are often readily exchanged between phages. One example of this modularity is the clustering of recombination functions from phage λ and P22 (a *Salmonella* phage). The phage P22 annealase called Erf (essential recombination function) cannot substitute for λ Beta in *E. coli*, and the P22 anti-RecBCD function modifies RecBCD's enzymatic activity and actually increases its affinity for dsDNA ends, while the λ Gam protein inhibits RecBCD from binding to dsDNA ends. Nonetheless, the λ Red system (three genes) and the P22 system (four genes) can efficiently substitute for one another in *E. coli* and *Salmonella* hosts.

Recombination reactions in these functional segments occur in short regions of homology between the modules, leading to sequence mosaicism in the lambdoid family of bacteriophages. λ Red-like systems are capable of recombining with short homologies very efficiently and thus would be expected to easily promote recombination among these modules during mixed phage infections. Furthermore, the Red system is also able to act on homeologous DNAs, recombining DNA that is only partially homologous (as much as 22% divergent). This ability gives lambdoid phages even greater capabilities to promote recombination within small regions of imperfect homology between functional modules. Such a relaxed requirement for DNA shuffling would give lambdoid phages an evolutionary advantage over other phages (and bacteria) that require high sequence identity for exchanging DNA segments.

DNA Repair

When phage DNA enters the cytoplasm of a bacterium in nature, restriction endonucleases often generate double-strand breaks in the viral chromosomal DNA. The dsDNA breaks inflicted by these restriction systems can be repaired by recombination with

another infecting phage. Heterologous prophages already resident in the cell may also participate in genetic recombination with the damaged DNA of the infecting phage, with portions of the broken chromosomes rescued by recombination and incorporated into resident prophages. It was, in fact, the *in vivo* delivery of a dsDNA break by a restriction enzyme during experimental phage λ crosses in the Stahl laboratory that demonstrated the importance of dsDNA ends for the action of λ Red *in vivo*.

DNA damage is the natural inducing agent for excision of lambdoid prophages from the bacterial chromosome, as a result of RecA co-protease-dependent *cI* repressor cleavage and subsequent expression of the phage lytic genes, including the recombination functions. A low level of DNA damage may allow transient expression of phage functions without inducing a full-fledged lytic cycle. Activation of the Red system through this transient prophage induction increases total cellular recombination potential, which may benefit the bacterial host by providing an additional DNA repair pathway. Transient prophage induction would also increase the likelihood that double-strand breaks in the phage DNA will be rescued by other prophages of the same type or by heterologous prophages with limited homology. Under some circumstances a partially induced prophage may undergo DNA replication while still integrated in the *E. coli* chromosome, giving rise to onion-skin replication, a replication bubble with multiple replication forks. Exo and Beta may act to resolve these kinds of aberrant structures.

Classical Models of λ Recombination

After nearly three decades of research involving the Red system, two general mechanisms of λ homologous recombination have been defined. One mechanism is the RecA-dependent pathway of Red recombination, which occurs when phage chromosomes are prevented from replicating. In delineating this pathway, crosses were performed with λ mutants defective for genes responsible for the initiation of chromosomal replication. As noted above, the loss of RecA drastically reduced recombination in such crosses. By this mechanism, it is thought that the Red proteins Exo and Beta act on dsDNA ends to generate ssDNA, where the bound Beta protein is replaced by RecA, with assistance of host *recFOR* proteins (functions normally associated with loading RecA onto ssDNA coated with *E. coli*'s single-stranded binding protein). This intermediate is then shuttled into the host pathway of homologous recombination, involving both branch migration proteins and Holliday junction resolvases of the host (though the phage resolvase Rap could also play a role).

The second major mechanism of Red recombination is the RecA-independent ssDNA annealing pathway. This route is best described in the context of the rolling-circle mode of chromosomal replication (also called the sigma, or σ , mode), as mentioned above. Such rolling-circle intermediates are thought to be initiated by random nicks in a λ chromosome replicating in the circle-to-circle mode (also called the theta, or θ , mode), which consequently generates dsDNA ends that are distributed across all regions of the λ chromosome. Thus, in this scenario, the ends of two rolling-circle intermediates are acted upon by λ Exo and Beta to produce ssDNA coated with Beta protein. Complementary regions of this ssDNA are then annealed together by the action of λ Beta to form a larger heteroduplex recombinant DNA intermediate. After DNA polymerase I fills the remaining ssDNA gaps, the nicks are sealed by DNA ligase. Thus, the recombination event promotes both genetic diversity in a heterogenic community, as well as formation of large concatemeric DNAs refractory to exonuclease degradation for more efficient packaging.

Development of Recombineering

By the late 1990s, it was recognized that the λ Red system might be useful to promote genetic engineering of the *E. coli* chromosome, by virtue of its ability to promote recombination between linear dsDNA substrates and bacterial chromosomes. It was theorized that the Red and Gam functions, if expressed off a plasmid independent of any other phage functions, might create a hyper-recombinogenic environment in *E. coli*, and perhaps other hosts as well, including pathogenic bacteria. Experiments performed by one of us (KM) showed that this was indeed the case. Plasmid-borne expression of Red and Gam in an *E. coli* strain resulted in a strain that could be transformed with linear DNA substrates at very high efficiency. Furthermore, the hyper-rec background of these strains facilitated the insertion of a PCR-amplified linear dsDNA antibiotic resistance gene, flanked on each side by 1 kb homologies to the target gene, at efficiencies up to 100-fold higher when compared to other recombination-proficient strains used at that time. Around the same time, the Francis Stewart laboratory was working with another phage homologous recombination system, the RecET system of the cryptic Rac prophage. This system, which is analogous to the λ Red system, possesses a 5'-3' dsDNA exonuclease (RecE) and a single-strand annealing protein (RecT). Although λ Exo and RecE have similar activities, the full length RecE protein is much larger (nearly 900 amino acids), with the exonuclease activity in the C-terminal domain. The Stewart lab demonstrated that RecET could also promote recombination between bacterial genomic DNA and PCR substrates, but this time with target homologies of about 50 bp. This was a key step in the development of recombineering technologies. This relaxed requirement for the size of flanking homologies allows the preparation of dsDNA substrates to be performed by PCR, where a drug marker serves as a template and flanking homologies are simply added to the 5' ends of the PCR primers. Plasmid constructs containing drug markers with long flanking homologies, typical of the early days of gene replacement in bacteria, were no longer required.

This novel gene replacement technology was quickly followed by similar reports from a number of laboratories. It was found that short flanking homologies (30–50 nt) on the linear dsDNA were adequate for the recombination for both the λ Red and RecET systems, though the former system showed mildly better efficiencies. Both systems required λ Gam for efficient gene replacement.

Fig. 1 Linear dsDNA recombineering with PCR-generated substrate. (a) Hybrid primers are designed that are ~70 nt long and contain ~50 nt of 5' homology that flank the intended target sequence. The remaining ~20 nt at the 3' ends prime the DNA template, in this case an antibiotic resistance gene (drug^R marker) indicated in blue. These hybrid primers are used in a PCR reaction to generate a linear dsDNA containing the amplified cassette with homology to the target gene at both ends. (b) The PCR product is used for recombineering (requiring both λ Beta and Exo) and will replace most of the endogenous DNA, indicated in black, between the two target homology sequences. (c) The final recombinant can be verified using two pairs of PCR primers, 1 + 2 and 3 + 4. These primer pairs will amplify the recombinant junctions between the target and the newly inserted DNA and confirm correct insertion. If the inserted DNA is a different size than the original endogenous sequence, primer pair 1 + 4 can be used to confirm that the recombinant strain contains only the modified copy of the gene and that the original sequence is no longer present. Primer pair 1 + 4 can also be used to amplify a PCR product for DNA sequencing.

The phage recombination functions plus Gam, either residing in the bacterial chromosome or encoded by a plasmid, are typically expressed from one of a number of controllable promoters. These promoters are normally inactive but can be up-regulated for gene expression by displacement of a bound repressor protein (e.g., LacI or AraC) from the operator by small molecule inducers (e.g., IPTG or arabinose, respectively), or by inactivation of a heat-labile repressor. The regulated expression of these recombineering functions is important, as constitutive high levels of expression result in poor growth and can be mutagenic. Once induced, the phage recombination functions promote a hyper-recombinogenic environment, where linear DNA species recombine with target chromosomal or episomal sequences at very high frequencies. The DNA substrates can be dsDNA that is either generated by PCR or chemically synthesized, or single-stranded DNA oligonucleotides.

To perform recombineering, the cells are grown to moderate density, the recombination functions are induced, the cells are collected by centrifugation and washed, and linear DNA donor substrates are introduced into the bacteria by electroporation. The cells are then suspended in liquid media and grown for a period of time, to allow recombination between the introduced substrate and its target chromosome (or episome), and to promote expression of any antibiotic resistance cassette. The cells are then plated on petri plates under appropriate conditions to recover recombinants; most often an antibiotic selection is applied. Recombineering is efficient, precise, and accurate. The ease and speed of the process has made it the method of choice for genetic engineers to alter bacterial chromosomes, study bacterial pathogenesis, perform metabolic engineering of industrially-important bacteria, or manipulate eukaryotic DNA cloned into plasmids and bacterial artificial chromosomes (BACs).

Recombineering With dsDNA

The most common type of genetic modification constructed with recombineering is a simple gene replacement, where the target gene is replaced by a DNA cassette conferring drug resistance. For this purpose, a PCR is used to generate linear dsDNA where the targeting homologies are incorporated into the 5' ends of the PCR primers (Fig. 1). The PCR products are made using chimeric (hybrid) primers of about 70 nt in length. The 5' ends provide ~50 nt of homology to the target DNA and the 3' ends provide ~20–25 nt of priming sequence to amplify the drug^R cassette. Although the template for PCR can theoretically be a drug^R marker contained on a plasmid, care must be taken to prevent carryover of the supercoiled template plasmid from the PCR reaction, leading to false positive recombinants following electroporation. Treating the PCR with the restriction enzyme *DpnI* can minimize template carryover, as it is active only on methylated DNA and will not digest PCR products. Other appropriate templates for PCRs used in recombineering include drug-resistant markers on conditionally-replicating plasmids, or bacterial colonies or cultures. For the latter, a small portion of a medium-sized colony, or several microliters of an overnight culture, will serve well as a template in a

Fig. 2 Two-step selection/counterselection procedure to generate unmarked gene knockouts. (a) A linear dsDNA dual cassette containing two adjacent genes, one encoding drug resistance (indicated in cyan) and the other a counterselectable maker, *i.e.*, *sacB* (indicated in yellow) is generated using PCR with hybrid primers that provide flanking homologies to the desired target, as described in Fig. 1. (b) In the first recombineering step, the linear dsDNA dual cassette is inserted at the desired target, and selection for drug resistance is applied. (c) In the second recombineering step, a linear dsDNA substrate containing the final desired DNA sequence (in red) with flanking homologies is provided. Application of the counterselection allows recovery of recombinants in which the dual cassette has been replaced with the desired DNA. (d) As described in Fig. 3, the final recombinant should be verified with the appropriate PCR reactions and by DNA sequencing.

standard PCR to generate recombineering substrates, provided the PCR program contains an initial (95°C) heating cycle to lyse the cells prior to cycling. To this end, the Court laboratory has engineered a useful bacterial strain called T-SACK, which contains most of the drug-resistant markers typically used for recombineering in *E. coli*. Contained in this strain are the genes *tetA* (Tet^R), *sacB* (sucrose^S), *bla* (Amp^R), *cat* (Cam^R), and *kan* (Kan^R), making this a useful single source for the variety of drug-resistant markers used for recombineering. Use of the T-SACK strain as a PCR template for drug^R dsDNA markers is preferable to using a plasmid template, since the possibility of false positives resulting from contamination by residual supercoiled plasmid template is eliminated. The error-prone Taq polymerase is suitable for this PCR, as any errors generated in amplifying the drug^R cassette will not appear on the antibiotic selection plate.

Markerless Gene Deletions and Counterselection Schemes

Linear dsDNA recombineering can also be used in a two-step selection/counterselection method (Fig. 2), if it is undesirable for an antibiotic resistance gene to remain in the final construct. Several dual cassettes with two genes are commonly used; these cassettes contain a drug marker linked to a second gene whose function can be selected against. The *sacB* gene from *Bacillus subtilis* is frequently used as a counterselection marker, since bacteria containing this gene are unable to grow on solid agar medium containing sucrose. The *sacB* gene has been linked to several different drug markers, to generate selection/counterselection dual cassettes. Other counterselectable genes can also be used, including the wild type *rpsL* gene in a *rpsL31* (strep^R) mutant (where loss of the overexpressed WT *rpsL* gene confers streptomycin resistance) and *tolC* (resistance to colicin E1). In the first recombineering step, the drug resistance encoded by the dual cassette is selected, and the cells are tested to verify that the counterselectable function is expressed. In the second recombineering step, the counterselectable function is selected against, allowing the dual cassette to be replaced with the desired genetic alteration, which may be either a net deletion/small insertion created with a ssDNA oligo, or any desired dsDNA sequence created with a PCR or synthetically designed substrate. This method is useful to insert non-selectable pieces of DNA such as gene tags (*i.e.*, *gfp*). Replacement of the dual cassette is confirmed using PCR analysis and final constructs are verified by DNA sequencing.

Recombineering With ssDNA

The simplest recombineering reaction uses linear ssDNA, usually provided as synthetic DNA oligonucleotides (oligos). For oligo-mediated recombineering, only the expression of λ Beta is required, as the substrate is already single-stranded, *i.e.*, λ Exo is not needed. For oligo-mediated recombineering, ~70 nt ssDNA oligos are optimal in length, with the desired base change(s) in the center of the linear DNA. In wild type *E. coli* cells, oligos yield recombinants at a frequency of about 1 out of 1000 total cells. Thus, a selection scheme is usually required for single base changes, insertions, or deletions. However, the Court lab found that the

frequency of oligo-mediated recombineering can be increased ~100-fold by using strains that are deficient for methyl-directed mismatch repair (MMR), providing further evidence of a mechanistic link between λ Red and host DNA replication machinery. In the absence of MMR, point mutations and changes of a few bases can be made very easily, with 30%–50% of the total viable cells (after outgrowth) containing the oligo-mediated mutation in its chromosome. The model for this mechanism is straightforward. When the ssDNA oligo anneals to the lagging strand template at the replication fork, mismatches present between the oligo and the template strand are recognized by the MMR system, and are corrected in favor of the wild-type DNA sequence. Thus, MMR mutants expressing λ Beta demonstrate higher rates of oligo-mediated recombineering.

However, because cells lacking MMR accumulate mutations, it is preferable to avoid use of such mutants as recombineering hosts. One method to bypass the MMR system is the use of oligos that generate C-C mismatches. Since these mismatches are not recognized by the MMR system in *E. coli*, oligos that generate this particular mismatch generate high frequency mutagenesis. The Court laboratory also found that when modifying genes, incorporation of base changes at several adjacent wobble codons near the desired nucleotide change allows evasion of an active MMR system and can be done without changing the amino acid sequence of a protein of interest. The ssDNA oligo design for this scheme generally results in a high frequency of recombinant formation, even in MMR⁺ bacteria. Other measures to avoid MMR involve the co-expression of dominant negative mutations of Dam methylase or the mismatch recognition function MutS along with λ Beta protein during the induction period. In these circumstances, the inhibition of the MMR system is transient, allowing the oligo to avoid correction for just a short recombinogenic window, leaving MMR system intact for the outgrowth period. When MMR is avoided, high efficiency genetic alterations are possible with oligo recombineering, including single point mutations and small changes of a few base pairs. Large deletions of more than several kb can also be made with ssDNA oligos, but the efficiency of this reaction is much lower and generally requires a selection.

In vivo Cloning

Another useful dsDNA recombineering reaction mediated by the Red system is a recombination reaction that results in a bacterial segment of genomic DNA being incorporated into an electroporated plasmid backbone to form an intact replicating plasmid. It is a method to clone large segments of bacterial chromosomes, or eukaryotic DNA from BAC libraries, without the use of restriction enzymes or PCR, a procedure called *in vivo* cloning. This is especially useful for cloning large sizes of chromosomal segments, where classical methods of restriction enzymes digestion and ligation are not feasible as a result of the lack of unique cutting sites. To perform *in vivo* cloning, a DNA plasmid backbone containing, at a minimum, the origin of DNA replication and a drug^R selection marker, is amplified using chimeric primers. The 5' ends of these primers provide homology to the target DNA to be retrieved, and the 3' ends prime the plasmid DNA sequence (Fig. 3). Cloning by retrieval is a low efficiency reaction but is easily selected for by plating on antibiotic-containing selection plates. The advantage of *in vivo* cloning is that segments of the bacterial genome are cloned without subjecting them to a PCR, which might otherwise introduce polymerase errors. Instead, once retrieved from the chromosome and inserted into the vector backbone, the insert replicates using the high-fidelity system of the *E. coli* replisome (and its proofreading capabilities). Any errors that might persist in the wake of the replisome are caught by the MMR system. The most common false positives occurring with *in vivo* cloning arise when the electroporated plasmid recircularizes without the insert, often as a result of recombination between micro-homologies that exist in the terminal ends of the vector. Such false positives can be minimized by careful design of the homologous sequences to the chromosomal target region, in order to avoid such micro-homologies. Control transformations in the absence of the recombination functions should be done to verify that the plasmid backbone does not circularize at high efficiency without incorporating the desired insertion.

The Stewart laboratory found that the RecET system is superior to λ Red for one type of *in vivo* cloning: the joining of multiple linear dsDNAs containing short terminal homologies to form intact circular plasmids. Recombination occurs at the DNA ends and depends on homology rather than on restriction sites, giving flexibility in plasmid design. For reasons that are not understood, the full length RecE protein is required for this linear DNA assembly to occur at high efficiency.

Mechanism of Oligo-Mediated Recombineering

Oligo-mediated recombineering requires only a single function, a ssDNA annealing protein, Beta or RecT. For any chromosomal target, there are two alternative sequences for a recombinogenic oligo: one targeting either the leading strand or the lagging strand templates. It was observed that for these two complementary substrates, one oligo gave a ~20-fold higher recombination frequency relative to the other. This difference correlates with the direction of DNA replication through the target site, and the higher efficiency oligo is complementary to the lagging strand template. This observation suggested that the recombination is occurring at the DNA replication fork, with oligos annealing to the lagging strand template at single-strand gaps present in the newly synthesized discontinuous lagging strand, as illustrated in Fig. 4. In effect, the oligo becomes a pseudo-Okazaki fragment, with filling-in of the gap behind the 5' end and extension from the 3' end performed by DNA polymerase I, so that the oligo is incorporated into the growing new daughter strand. Subsequent work from several laboratories strengthened the evidence that in

Fig. 3 *In vivo* cloning by retrieval. To retrieve a gene or other DNA sequence from the bacterial chromosome, hybrid primers, shown in black, are used to amplify a plasmid backbone, indicated in gray, containing an origin of DNA replication (*ori*) and usually an antibiotic resistance gene to allow for plasmid selection. The hybrid primers should be designed with the two homology sequences (indicated in green and red) facing inward, so that when the recombination between the plasmid backbone and the bacterial DNA occurs, the desired DNA sequence will be incorporated onto the plasmid backbone. DNA to be retrieved, 'Your Favorite Gene' (YFG, indicated in blue) is located on the bacterial chromosome or BAC. This reaction can also be used to create an intact circular plasmid from two or more PCR products.

Fig. 4 Model for single-strand DNA annealing at the DNA replication fork promoted by the λ Beta protein. A simplified schematic of a DNA replication fork is presented, with the leading and lagging strand templates in red and blue, respectively, and strand polarities indicated. The newly replicated leading and lagging strands are in black with the direction of DNA synthesis indicated by the arrowheads. Beta (or other single-strand annealing protein) binds a ssDNA oligonucleotide and anneals it to complementary DNA sequence on the lagging strand template in a gap that arises during discontinuous replication of the lagging strand. Beta may also anneal a complementary ssDNA oligo to single-strand DNA on the leading strand template ahead of the newly replicated leading strand, but this recombination is less efficient than a recombination event targeting the lagging strand.

order for recombinants to form, the circular DNA being targeted (either chromosome or plasmid) must be replicating, consistent with the idea that recombination occurs predominately by single-strand annealing, rather than by strand-invasion.

Mechanism of dsDNA Recombineering

Two laboratories have reported that dsDNA recombination likely proceeds through a single-stranded DNA intermediate. In this model, after a dsDNA substrate is introduced into the bacterial cell expressing λ Red, one strand is entirely removed by phage λ Exo, leaving the complementary ssDNA bound by the recombinase, which is then incorporated by single-strand annealing at the cellular target, much like the mechanism described above for oligo-mediated recombineering. The data for this mechanism is suggested by the fact that sequence information in the homologous regions for most recombinants following recombineering is usually derived from one of the two strands in the dsDNA substrate. This mechanism is likely to occur with short dsDNA substrates more often when compared to longer substrates, since λ Exo is a moderately processive (~ 3 kb) enzyme. However, the fact that this is not seen in all recombinants, and less so with long recombinants, suggests that another apparently less-favored mechanism is also at work.

Recombineering in Pathogenic Bacteria

Recombineering technology opened up the toolbox of genetic engineering in *E. coli*. The fact that the λ Red functions could be supplied from an episome suggested early on that the system might be amenable for use in clinically relevant bacteria, simply by transformation of a Red + Gam-producing plasmid into a clinical strain of interest. This proved to be the case, and the plasmid-borne

λ Red system has been used to make gene knockouts in enterohemorrhagic and enteropathogenic *E. coli*, for constructing vaccines in *Shigella* species, and to manipulate the chromosome of *Salmonella enterica*. The successful use of λ Red for genetic modification in these bacteria is not too surprising, given the genetic relatedness between these bacterial species and *E. coli* K12. In more distantly related bacteria such as *Pseudomonas* species, the λ Red system can work, but high efficiency requires longer regions of targeting homologies. Ideally, the use of recombineering technology in non-*E. coli* species is most successful when recombination systems from endogenous phage systems of the bacterium in question are found and characterized. This was the approach taken by the Hatfull lab when investigators there identified a RecET-like system in the mycobacterial phage Che9 and demonstrated its use in both dsDNA and oligo-mediated recombineering in *Mycobacterium smegmatis* and *Mycobacterium tuberculosis*. Other studies have identified λ Beta or RecT-like annealases in the chromosomes of diverse bacteria and have shown that they are capable of promoting oligo-mediated recombineering in *E. coli* at a wide range of efficiencies. A recent search of λ Beta-like proteins for use in the soil organism *Pseudomonas putida* revealed an annealase activity (the Ssr protein) capable of promoting oligo-mediated recombineering, setting the stage for further development of recombineering in the important strain, used often in metabolic engineering strategies. Similarly, a Beta-like W3 phage recombinase has recently been developed for use in the genus *Shewanella*, a metal-reducing bacterium important in bioremediation.

Combining Recombineering With Other Gene Modification Technologies

The gene-editing tool CRISPR has revolutionized the genetic toolbox for eukaryotic cells. In its simplest manifestation, RNA guides bring the Cas9 nuclease to the target gene to deliver an endonucleolytic double-strand cut at the desired location. Because of the presence of non-homologous end-joining (NHEJ) functions in eukaryotic cells, the cut is often repaired inefficiently by rejoining the dsDNA break after some nucleotide degradation occurs at the cut site, leading to gene inactivation. Bacteria typically lack NHEJ systems, and as such, cuts are either repaired by homologous recombination pathways, or not. In the latter case, the cut is lethal.

It was recognized that CRISPR could be used in bacteria, not for gene inactivation per se, but more importantly to select against non-recombinants following recombineering. The Marraffini lab combined the CRISPR-Cas9 technology of creating targeted *in-vivo* dsDNA breaks with Red-mediated oligo recombineering, using dsDNA cleavage as a counterselection step against unmodified chromosomes in *E. coli* and *Streptococcus pneumoniae*. This methodology drives up the frequency of oligo-mediated recombineering, where half of the total viable cells recovered were recombinants. Since this efficiency is so high, recombinants can be identified by DNA sequencing a few candidates, with no need for selections or screens. These experiments also suggested that Red recombination did not repair the double-strand break created by CRISPR-Cas9, and that Cas9-cleavage was acting solely as a counterselection step against non-recombinants (*i.e.*, parental DNA). Clearly, one requirement in using this combination of technologies is timing; that is, that the phage-mediated linear DNA recombination occurs before Cas9 cutting is activated.

In another manifestation of combining two separate technologies into one genetic modification scheme, oligo-mediated recombineering is used to deliver the P1 phage site-specific attachment site *loxP* to different regions of a bacterial chromosome, separated by 10 kb of DNA or more. Following this step, expression of the site-specific recombinase Cre will promote recombination between the two *loxP* sites, and depending on the relative orientation of these sites, will promote either inversion of the marked segment or its deletion. This has been a common practice in genome reduction strategies, and to identify essential regions of a bacterial genome. In a more recent example of a similar technology in *M. tuberculosis*, Che9 RecT-promoted oligo-mediated recombineering is coupled with the mycobacterial Bxb1 phage site-specific integration system. In this system called ORBIT (Oligo Recombineering followed by Bxb1 Integrase Targeting), the ssDNA oligo contains the Bxb1 phage *attP* site. The *attP*-containing oligo is co-electroporated with a non-replicating plasmid containing Bxb1 *attB*, a drug^R-marker, and a payload (*e.g.*, a *gfp* tag). In this system, the introduction of the *attP* site is followed by integration of the payload plasmid in the same outgrowth period. Thus, gene deletions or fusions can be made by co-electroporating an oligo with a ready-made target-independent plasmid. A major advantage of ORBIT is that no target-specific plasmids or PCR products need to be generated for the construction of gene knockouts or genetic fusions.

Recombinase-Independent Recombination

It has been observed that in some bacteria, electroporation of linear ssDNA substrates gives rise to recombinants that are independent of any known phage recombinase. While not strictly “recombineering”, there are similarities between this type of ssDNA recombination and ssDNA phage-mediated recombineering. B. Swingle and others have found that oligo-mediated recombinants can be found at a frequency of $10^4/10^8$ viable cells when high oligo concentrations are used. The recombination displays a lagging strand bias, and oligos targeting the lagging strand that escape mismatch repair give the highest efficiencies. Recombinase-independent oligo-mediated recombination has so far been demonstrated in *Pseudomonas syringae*, *E. coli*, *S. enterica*, *Shigella flexneri*, *Yersinia pseudotuberculosis*, *Legionella pneumophila* and *Shewanella oneidensis*. Recombinase-independent recombination provides a toe-hold for creating mutations in bacteria that lack recombineering systems, and thus affords a starting point for development of *in vivo* genetic engineering in these organisms. Although the frequencies of this recombinase-independent oligo incorporation are too low to allow direct screening for recombinants, the level of

Fig. 5 A flow-chart for recombineering. In all cases the desired genetic constructs should first be designed *in silico*. The appropriate linear DNA substrate and expression system will vary depending on the desired alteration. The outgrowth procedures and methods used to identify the recombinant clone will also differ.

recombination can be dramatically enhanced by using it in combination with CRISPR-Cas9 cutting. The dsDNA break created by Cas9 is used as a counterselection and enriches the recombinant class by eliminating non-recombinants, just as when CRISPR-Cas9 is coupled to canonical recombineering.

Final Thoughts

Over the last ~20 years the development of recombineering technology has revolutionized bacterial genetic engineering. Many papers have been published describing the various possible reactions and helping to elucidate molecular mechanisms involved in this bacteriophage-mediated recombination. A few seminal publications are listed in the following section. For those considering recombineering, a flow chart defining the necessary steps is provided in **Fig. 5**. While this article has described the present state of recombineering, it is a rapidly evolving field, since phages are the most abundant organisms in nature and new isolates are being characterized daily. Many of these newly identified phages will contain generalized recombination functions analogous to the Red and RecET systems; these newly identified functions have the potential to enable gene editing in their specific bacterial hosts.

Nomenclature

ATP Adenosine triphosphate

qRT-PCR Quantitative reverse transcription polymerase chain reaction

Glossary

ATPase gp16 gp16 is an enzyme that can catalyze the hydrolysis of ATP. The gp16 is a DNA packaging ATPase from the virus phi29.

Bacteriophage A virus that can infect and replicate within bacteria.

Biomotor/nanomotor A motor with size in nanometer scale functions to gear molecules moving forward.

Connector/nanopore A hollow channel or pore in nanometer scale for the translocation of molecules, also known as the portal.

Procapsid A preformed protein shell in the virus assembly stage of many bacteriophages.

Introduction

We are all surrounded by traditional macroscale motors including both combustion engines and electric motors. One might ask: can we downscale the way we think of motors to the nanoscale range? The possible applications of nanomotors in nanotechnology will be intriguing but different. However, when we look at the basic mechanisms of both the macroscale and the nanoscale motors, they show many striking parallels and similarities. Analogous to the macroscopic ones, biological nanomotors are manufactured from static modules or parts that form a framework for moving and transporting substrates. Even though the moving parts are not always restricted to rotary or revolving motion, some motors perform the linear motion. Moreover, both macroscopic and nanomotors work by repeating the same cyclical of steps over and over.

Active motion is a typical and prominent feature of life. Motion distinguishes living organisms from inanimate matter. Motion is action derived from motors. All important life activities rely on biomotors – macroscopic respiration, heartbeats, walking, speaking, blinking. Biomotors drive even microscopic DNA replication, DNA repair, RNA transcription, homologous recombination, intracellular transport, molecular transport, and viral assembly. Biomotors are powered by ATP. The amount of ATP produced and consumed by one person is close to body weight, which is 50–80 kg per day.

Biological nanomotors are nanoscale machines that convert a primary energy source to mechanical motion between active and framework components. Motor complexes are vital to biological systems, and they support efficient, directional motility for the transportation of cellular components. Due to the progress of structural biology – single molecule methods and biotechnology approaches – the understanding of the molecular basis of structure in biological movement has progressed to the point where we can start thinking about possible applications of biomotors in nanotechnology. The elegant and delicate structures of viral double-stranded (ds)DNA packaging motors have inspired their application in nanotechnology. For example, studies on the motor packaging RNA (pRNA) of bacterial phage phi29 has led to the emergence of the field of RNA nanotechnology for disease treatment (Fig. 1). With the discovery of the highly stable pRNA three-way junction (3WJ) motif (Fig. 1), the application for constructing multivalent RNA nanoparticles with high chemical and thermodynamic stability leads to the development of RNA nanotechnology. RNA nanotechnology is the bottom-up self-assembly of nanometer-scale RNA architectures that are composed mainly of RNA (Fig. 1). In RNA nanoparticles, the scaffolds, targeting ligands, and therapeutics miRNAs or siRNAs can be composed mainly of RNA (Fig. 1). While classical studies on RNA focus on intra-RNA interactions and 2D/3D structure, more recently, RNA nanotechnology has further extended to inter-RNA interaction and quaternary (4D) structure (Fig. 1). The resulting branched RNA nanoparticles are homogenous, uniform in size and shape, and can harbor different functionalities while retaining their tertiary folding and independent functionalities both in vitro and in vivo.

Another new approach for high potent drug development leads to the study of motor ATPase with high stoichiometry of homologous subunits (Fig. 2). Many ATPase biomotors contain six pRNA copies that can serve as drug targets ($Z = 6$); and inducing a single pRNA subunit inhibits the entire biomotor function ($K = 1$), resulting in high inhibition (Fig. 2(D)). Leading to the creation of a novel drug targeting strategy: increasing the number of subunits that are potential targets (changing Z) further improving drug efficiency. This idea is akin to series circuits, such as those in traditional Christmas lights, where if a single bulb stops working, the entire strand fails (Fig. 2(A)). In contrast, traditional drug development is analogous to parallel circuits'

challenge to circumvent, as a single bulb's failure has no effect on the rest of the strand. By addressing multicomponent systems more like series circuits, it may be possible to create ultra-high inhibitory drugs. The phi29 motor is part of a large ATPase family (AAA +) that was used to elucidate this potent drug inhibition mechanism. Drugs that target viral motors in this manner include rimantadine for influenza, ALLINI for HIV, and bedaquiline for tuberculosis (Fig. 2(E)).

Bacillus phi29 and *Escherichia T7* present themselves as one striking feature in double-stranded (dsDNA) tailed bacteriophages of the *Podoviridae* family. During replication and morphogenesis, they encapsulate and compress their genomic DNA with tremendous velocity into preformed protein shells, called procapsids, driven by hydrolysis of ATP. This energetically unfavorable translocation is accomplished by a viral nanomotor. The viral DNA packaging motor is composed of a few parts. The gearing components are the first; and the second is the motor structure frame, such as the force generation ATPase. The third is the essential components of connector complex that is a dodecameric structure with a central channel (30–60 Å) through which viral DNA is packaged into the capsid and exits during infection. Though the portal proteins from different viruses have little sequence homology and large variation in molecular weight, portal complexes show significant morphological similarities. Yet, the portal connector of phi29 is bound with both ATPase gp16 and prohead RNA (pRNA). Binding of gp16 to the packaging motor relies on the association of pRNA because the central domain of pRNA is there for connector binding, and the 5'/3' paired helical region for recruitment of gp16. In phi29, moreover, the structure of one phage portal protein has been determined at atomic resolution. The connector ring consists of a twelve α -helical subunit, with three long helices of each subunit forming the central channel. The ring is 138 Å across at its wide end and 66 Å at the narrow end. The internal channel is 60 Å at the top and 36 Å at the bottom. The wider end of the connector is located in the prohead and its narrow end partially protrudes out of the capsid. The connector is located at the five-fold vertex of the viral capsid, which leads to a symmetry mismatch between capsid and the portal connector.

Extensive investigation of the group of dsDNA viruses reveals that all DNA packaging motors known so far involve two nonstructural components typical of ATPase. Further scrutiny has found these two proteins can be classified into two categories according to their roles and sizes. One category with larger size is for procapsid binding, such as gp16 of phi29, gpA of λ , gp12 of

Fig. 2 Biomotors have high stoichiometry of homologous subunits. phi21, gp17 of T4, and gp19 of T3/T7. The second category is the smaller-size protein for DNA binding and processing. This group includes gp16 of T4, gp18 of T3/T7, gpNu1 of λ , and gp1 of phi21. The DNA-packaging reaction is prohead and DNA dependent. One ATP is used for the packaging of two base pairs of DNA. Emerging information reveals that the mechanism of herpes virus DNA packaging is very similar to that of phages.

General structures of phage dsDNA motors include channels and DNA packaging enzymes (Fig. 3). The tailed-bacteriophage assembles the channel into an oligomeric-ring portal (connector), which is composed of 12 protein subunits and embedded in the pentagonal portal vertex of the procapsid. The phi29 connector has a truncated cone-shape. The connector functions as a nucleation point for the assembly of motor components. Both the DNA-packaging enzyme gp16 and pRNA bind the connector. Binding of gp16 to the packaging motor relies on binding of pRNA because the central domain of pRNA is for connector binding, and the 5'/3' paired helical region for recruitment of gp16.

The ingenious structures and functions of the phage biomotors have inspired us to develop nanobiotechnology for medical application. As RNA is a building block in nanotechnology, phi29 pRNA can be used to construct nanoparticle vehicles to deliver various therapeutics to the target cells for treatment of cancers, viral infections, and some genetic diseases. The phi29 DNA-packaging motor can be engineered and embedded into cell membrane to generate a pore for molecular sensing and drug delivery to the target cells for precision medicine. In this work, we intend to delineate the revolving mechanism of the biomotors in bacteriophages, with an emphasis on phi29. With our understanding of the dsDNA translocation mechanism by the phi29 packaging motor, we introduce the application of the packaging motors, especially the motor connectors, in single pore sensing of DNA, RNA, chemicals and proteins.

The nanomotors play significant roles in many biological processes as described above. The phage DNA packaging motors, such as phi29, SPP1, T4, and T7, package their DNAs into the procapsid during genome replication. Herein, due to space limitation, we will use the phi29-gp10 revolution motor as an example to explain how it packages its genome into the procapsid. From the movement mode, the nanomotors can be classified into linear, rotation, and revolution categories. (Please refer to the further reading list to acquire more knowledge on the mechanism of different biomotors). Fig. 4 shows the structure of several revolution nanomotors. Generally speaking, revolution nanomotors have larger size channel with left-handed chirality. Fig. 3 shows a simplified illustration of the mechanisms for the revolution motor of phi29 to drive unidirectional translocation of dsDNA. Briefly, the ring-shaped ATPase present on pRNA binds ATP to trigger the conformational changes of the ATPase subunit to revolve the dsDNA and move it forward. The phi29 gp10 connector has a large diameter and the narrowest part in the channel is ~ 3.6 nm to allow the translocation of dsDNA into the procapsid. The movement of the dsDNA around the motor is similar to how the

Earth revolves around the Sun but without self-rotation of the Earth, which avoids the coiling and tangling that happens in large or lengthy DNAs. From this DNA packaging process, researchers determined that the biomotors drive unidirectional DNA passage through the nanopore into the procapsid.

The single pore sensing is derived from the natural phenomenon of viral DNA packaging. Scientists have discovered that analytes can be driven through the extracted nanopore and each generates a unique electric signal with applied voltage. The proof-of-concept about the nanopore sensing was initially demonstrated by the inspection of DNA translocation through the α -hemolysin nanopore in 1996. In their research, the qRT-PCR verified the successful translocation of the single-stranded DNA (ssDNA) that was able to be driven electronically through the α -hemolysin nanochannel. To date, the nanopore sensing has been developed for different analyte detection as it has many advantages as an analytical tool. First, the detection is label- and amplification-free. Second, it can achieve the single-molecule detection with high specificity and sensitivity and offer real-time identification. Third, it only requires small analyte sample volumes (μ L range) and low concentrations (nM or pM range) for analysis. In the following paragraphs, we will summarize the third type revolving motor mechanism and the application of these motors in single molecule nanopore sensing.

The Revolving Mechanism of Biomotors in Bacteriophages

The Revolution Mechanism Without Rotation Common to the dsDNA Packaging Motors of all the dsDNA Bacteriophages

During replication, the dsDNA viruses translocate their genomic DNA into procapsids using the same mechanism by the nanomotors with ATP as an energy source in an entropically unfavorable process. The force generation mechanism of the bacteriophage packaging motors of phi29, HK97, SPP1, P22, T4, and T7 share the following common revolution mechanism without rotation. The 30° left-handed twist of the channel wall causes an anti-parallel arrangement with the right-handed helix of the dsDNA, leading to one-orientation trend (Fig. 3(B) and (C)). The same twist has been found in motor channels of all dsDNA viruses known so far including phi29, HK97, SPP1, P22, T4, and T7, of which their primary amino acid sequences were non-conserved, but the higher structures of the swivel were impeccably conserved and aligned. One-direction flow loops inside the channel of SPP1 and phi29 help a one-directional processing for the one-way translocation of dsDNA. The electropositive-lysine layers present in all the phage channels interact with one strand of the electronegative-dsDNA phosphate backbone, causing a relaying contact and transitional pausing during dsDNA translocation. In April of 2020, Xiangxi Wang, Hongrong Liu and Zihe Rao reported a high-resolution structural and mechanism of the ATP-driven DNA packaging motor of the double-stranded herpesvirus. The structure clearly shows that the herpesvirus DNA packaging motor is a hexamer exercising the revolution mechanism instead of rotation (Fig. 4(A)). The elucidation of the structural ends the 20-year fervent debate on whether the stoichiometry of the genome packaging motor of dsDNA viruses is pentamer or hexamer, or whether the motion process is rotating or revolving. Like the architecture of the phage packaging motors (Fig. 4(A)), a hexameric ring structure of the herpesvirus DNA packaging complex suggests that the motor translocates dsDNA by a sequential revolution mechanism with the aid of a transacting arginine fingers essential for ATP hydrolysis and DNA translocation. Astonishingly, the human viral motor has the structural properties similar to the bacteriophage motors, implying that the sequential DNA translocation via revolving motion is common during viral motor evolution in both eukaryotic and prokaryotic systems.

Besprozvannaya, M., Burton, B.M., 2014. Do the same traffic rules apply Directional chromosome segregation by SpoIIIE and FtsK. Molecular Microbiology 4, 599–608.

Revolving Mechanisms Determined by Motor Channel Sizes

For dsDNA to rotate through the center of the motor channel, the channel needs to have a size similar to the diameter of dsDNA, 2 nm. Thus, the channel diameter should be approximately 2 nm for dsDNA or 1 nm for ssDNA. For dsDNA to revolve through the motors, dsDNA moves by touching the channel wall rather than proceeding through the center of the channel. Accordingly, the channel diameter should be much larger than the dsDNA's to ensure sufficient room for revolution. The crystal structures and cryoelectron microscopy studies on the connectors of the T7, phi29 and other phages demonstrate that the channel diameters of the revolution motors are >3.5 nm, and those of rotation motors such as helicase and DNA polymerase is < 2 nm. **Fig. 4(B)** shows several rotating motors with smaller channel but revolving motors with larger channel. The revolution of dsDNA along the hexameric ATPase ring has the following parameters: the width of dsDNA helix is 2 nm while the diameters of the narrowest regions of the dodecameric portals of all the connector channels of phi29 SPP1, T4, T7, HK97, and FtsK are 3–5 nm. Even a herpesvirus motor complex forms a central channel with an internal diameter of 3.9 nm, greater than that of dsDNA as revealed by Cryo-electron microscopy (**Fig. 4(A)**).

Revolving Motors Distinguished by Chirality

The anti-parallel arrangement between the phi29 connector subunit and the DNA helices can facilitate dsDNA to revolve in single direction. All 12 subunits of the phi29 connector portal protein, relative to the vertical axis of the channel, tilt at a 30° left-handed angle to form the channel with a configuration anti-parallel to the right-hand dsDNA helix during packaging. This structural arrangement significantly facilitates the controlled motion, providing evidence for dsDNA revolving, instead of rotating, through the connector channel. The revolution neither produces coiling, or torsion force, nor touches each of the 12 connector subunits in 12 discrete steps of 30° transitions for each helical pitch. Fig. 5 demonstrates examples of rotating motors with right-handed channel whereas revolving motors with left-handed channel.

Special Aspects of Revolving Motor Actions

Force generation and energy conversion Several primary chemo-mechanical coupling mechanisms exist in all biomotors studied so far. By these mechanisms, the cycles of nucleotide binding and hydrolysis are coupled to conformational entropy rearrangements of the substrate-binding subunits of the motors. In the sequential mechanism, individual ATP binding and hydrolysis events proceed sequentially. For the concerted mechanism, all active sites on the motors simultaneously hydrolyze ATP. Of the stochastic mechanism, the ATPase sites randomly hydrolyze ATP. For all three mechanisms, ATP binding to the disordered subunits of ATPase stimulates conformational alterations of the ATPase with the entropy change. This fastens the bound ATPase at a less random configuration than the unbound ATPase. Such new conformation entropy facilitates the ATPase subunits to bind dsDNA and to prime ATP hydrolysis. ATP hydrolysis by the ATPase triggers the subsequent entropic and conformational changes. These alterations render the ATPase a low affinity for the dsDNA substrates, thereby leaving dsDNA to the next ATP-bound subunit that has a high affinity with dsDNA. These repetitive actions cause dsDNA to revolve around the subunits through the interior channel of the motor.

Unidirectional dsDNA translocation The translocation direction of dsDNA is controlled by five factors in phi29 motor (Fig. 3). First, ATPase experiences a chain of entropy transitions and conformational changes during ATP and dsDNA binding. ATP hydrolysis causes additional change in entropy and conformation of the ATPase, including the one with a low affinity for dsDNA that pushes dsDNA away and revolves inside the channel. Second, the 30° angle of each subunit of the dodecameric connector channel is anti-parallel to dsDNA, matching with the 12 subunits of the connector channel ($360^\circ \div 12 = 30^\circ$), as shown by crystallography (Figs. 3 and 5). Third, the internal channel loops have the unidirectional flowing property acting as a ratchet valve to avoid dsDNA reversal. Fourth, the $5' - 3'$ single-directional revolution of one strand of dsDNA goes along the connector channel wall. Fifth, the electrostatic force occurs from the relaying interaction of the electropositive-lysine layers with the electronegative-DNA phosphate backbone. Altogether, dsDNA is translocated in one direction by the multiple factors.

Communication/interaction between motor subunits for sequential action In the phi29 motor, a sequential action of both the pRNA and the ATPase gp16 was reported. Particularly, the subunits of ATPase act sequentially and cooperatively. The arginine finger motif plays a role in communication and interaction among the subunits by bridging dimer formation (Fig. 3(D)). Communication between

Fig. 5 Different chiralities of rotating and revolving motors. Rotating biomotors exhibit right-handed chirality to drive the right-handed dsDNA similar to the nut driving the bolt or the screwdriver turning the screw, whereas revolving biomotors exhibit left-handed chirality within the channel. Crystal structure analysis of viral DNA packaging motors reveals that this class of biomotors package DNA using the revolving mechanism. Reprinted with permission from Guo, P., Grainge, I., Zhao, Z., Vieweger, M., 2014. Two classes of nucleic acid translocation motors: Rotation and revolution without rotation. *Cell and Bioscience* 4, 54. Copyright 2014 Springer Nature. and De-Donatis, G.M., Zhao, Z., Wang, S., *et al.*, 2014. Finding of widespread viral and bacterial revolution dsDNA translocation motors distinct from rotation motors by channel chirality and size. *Cell and Bioscience* 4, 30. Copyright 2014 Springer Nature.

each two neighboring subunits is mediated by the finger. Such communication causes an asymmetrical hexameric organization, consistent with the asymmetrical structures in other hexameric ATPase systems. Thus, the arginine finger acts as a bridge between two subunits to form a transient dimeric subunit. Specifically, the arginine finger, located at the interface of two subunits of gp16, extends into the ATP binding pocket of the downstream subunit. The asymmetrical appearance of one dimer and four monomers in high-resolution structural complexes provide evidence for the mechanisms by which the arginine finger promotes inter-subunit interactions and sequential movements of individual subunits. The arginine finger is important for regulating energy transduction and motor function (Fig. 3(D)).

The Application of Bacteriophage DNA Packaging Motors in Single Pore Sensing of DNA, RNA, Chemicals, and Proteins

The single pore sensing technique has built up a powerful platform for numerous applications including the detection of DNAs, peptides, and chemicals. Prior to discussing the use of nanopores for single-molecule sensing, we present background information about the history of single molecule sensing. The well-known biological connectors found in bacteriophages include the phi29, SPP1, T4, P22, and T7. The following lists several well-studied connectors.

Phi29 Connector

The phi29 connector was the first portal protein with the atomic structure solved. The connector consists of 12 protein subunits (gp10) that form a ring-like truncated cone structure. The molecular weight for each subunit is 36 kDa. The end diameters of the cone structure are 6.6 and 13.8 nm, with the wider and narrower ends termed the C- and N-terminals, respectively. The area of the narrowest part of the inner channel is 10 nm², which corresponds to a diameter of ~3.6 nm. In bacteriophage phi29, the C-terminal is located in the procapsid, and translocation of dsDNA during packaging is unidirectional from the N-terminal to C-terminal. The clip region in the phi29 connector can bind with pRNA to help with the DNA packaging. In addition, the negatively charged residues, aspartate and glutamate in the channel, have the potential to keep the DNA in the center of the channel; this central localization is necessary for the phi29 DNA packaging. The phi29 nanochannel also has the positively charged residues, such as lysine and arginine, which can attract the DNA and hence prevent the DNA from slipping out.

SPP1 Connector

There are four domains in the SPP1 connector: clip, stem, wing, and crown. This connector has 13 protein subunits (gp6) that assemble into a cone structure similar to the phi29 connector, with a total molecular weight of 745 kDa. The overall diameter of the SPP1 nanochannel is ~16.5 nm with a height of ~11 nm. The most constricted part in the tunnel is ~2.7 nm. The negatively and positively charged residues in the SPP1 channel are also required for DNA packaging similar to those of the phi 29 motor.

T7 Connector

The T7 connector is formed by 12 protein subunits with a molecular weight of 59 kDa for each subunit. The channel length is 13.1 nm, with external diameters ranging from 5.9 to 17.3 nm. The most restricted region in the T7 interior channel is 3.9 nm, which is relatively wide compared to the other types of bacteriophage connectors. The lysine residue in the stem domain of T7 nanochannel is highly possible to interact with the phosphate backbone to help with DNA translocation.

Apart from phi29, SPP1, and T7 connectors, many other phage connectors such as T3, T4, and P22 were studied. Generally, the phage connectors consist of about 11–13 subunits of proteins, with their height and width on the order of 10's nm and inner diameter within 4 nm.

Over the years, the nanopore-based sensing technique has been developed for the detection of various molecules and has proven its potential for the medical diagnosis of diseases. The following sections discuss the mechanisms and provide examples of single-molecule sensing using nanopores. Please note that we will focus on the discussion of the biological nanopores from bacteriophages in this article. For information on other types of nanopores, please refer to the further reading list.

The Mechanism of Single Pore Sensing

The general mechanism of biological nanopore sensing is based on the resistive pulse technique. Fig. 6(A) shows a schematic diagram of the technique. Briefly, the purified connector is inserted into the lipid bilayer membrane to form the nanopore channel. Voltage is applied across the membrane, which allows ions to pass freely through the channel. When analytes are translocated through the membrane, ion flow is affected. This results in a change to the current and creates fingerprinting signals. Commonly used electronic signatures that help identify different analytes include the current blockage and dwell time. The current blockage represents the percentage of the blocked current relative to the open current of the nanopore channel, while the dwell time measures the length of time the current blockage lasts.

(D) Haque, F., Wang, S., Stites, C., *et al.*, 2015. Single pore translocation of folded, double-stranded, and tetra-stranded DNA through channel of bacteriophage phi29 DNA packaging motor. *Biomaterials* 53, 744–752.

As analytes are driven to translocate or interact with the connector by electric force, many things may affect current blockage and dwell time. These things include intrinsic properties of the targets such as their shape, length, charge, hydrophobicity, or hydrophilicity, as well as the type and modification of the analytes. First, analytes that are smaller than the nanopore may be translocated through the channel to generate electric signatures, and different samples have the potential to generate different signals. Second, analytes that are larger than the diameter of the nanopore cannot pass through the channel due to size limitations. Theoretically, larger analytes or those with longer chains will block more current signals and have a longer dwell time than smaller analytes. In addition, stronger interactions between the analytes and the connector can produce longer dwell times than those have weaker interactions with the nanopore. Moreover, some analytes can interact with the connector on one side and induce conformational changes to the connector, thus generating distinct electric signals without translocation. Since only specific types of analytes can trigger conformational changes to the connector and cause current blockages with different dwell times, this becomes a technique for analyte determination. In both cases concerning small and large analytes, the type and modification of the connector can greatly affect the electric signals. For instance, a larger nanopore can allow larger analytes to be translocated through the pore, while smaller nanopore channels do not. Moreover, modification of the nanopores, such as site-directed mutagenesis or introducing ligands into the nanopore, can significantly influence the interactions between the analytes and the nanopore, resulting in different electric signals. For example, introducing more hydrophobic groups into the nanopore can increase the dwell time for samples with many hydrophobic groups. Please refer to the further reading list for additional information on the modification of the connector for nanopore-based sensing techniques.

In conclusion, biological nanopore sensing is based on distinct electric signatures generated when analytes pass through or interact with the nanopore. The intrinsic properties of the analytes and the nanopore determine the fingerprinting signals, which allow for the differentiation and identification of unique analytes.

Applications of the Biological Nanopore Channel as a Conduit for Single Pore Sensing

As mentioned in the nanopore detection mechanism section above, different analytes can generate distinctive electric signals to be distinguished from the background. The following sub-sections will address several experimental examples to explain the single pore sensing technique further.

The sensing of DNA: DNA carries genetic information and is imperative for all lives. Recognizing the variations in different types of DNA may help people better elucidate their functions, which can benefit the diagnosis of diseases in their early stages, and further assist in the treatment of these diseases.

The single pore sensing of DNA recognizes that different size and conformation can cause various current blockage events. The phi29 gp10 connector has been shown for the differentiation of dsDNA with different conformations by Haque and coworkers. In the experiment, Haque *et al.* examined the translocation and analyzed the current blockage of the folded 5 kbp dsDNA. Fig. 6 shows the current signatures for the dsDNA with different conformations that caused distinct blocking events. The straight dsDNA caused a single level blockage $\sim 32\%$, while the tetra-stranded complex with two dsDNA geared into nanostructure blocked the channel current with $\sim 64\%$. Additionally, the dsDNA and tetra-stranded DNA (tsDNA) also showed difference in their current blockage events. In short, the dsDNA mainly caused the 32% current blockage events whereas the tsDNA produced both the 32% and 64% blockage events. These experiments fortify a foundation for future studies on the detection of biomarkers from the conformational changes.

The sensing of RNA: Different types of RNAs have been found to be able to serve as the biomarkers for diseases diagnosis, demonstrating their importance to lives.

Currently, the sensing of RNAs with bacteriophage nanopores is at the beginning stage. The work in the detection of single-stranded RNA (ssRNA) with a modified phi29 nanopore has promoted the application of bacteriophage connectors in RNA detection. Geng *et al.* determined that the removal of the internal loop segment of phi29 channel could create a modified channel with a cross-sectional area about 40% less than that for the wild-type phi29 connector. The translocation of ssRNA was able to be identified by the modified phi29 connector, which resulted in $\sim 20\%$ current blockage. Their experiments suggested that the modification of nanochannels could achieve different detection purposes. Please refer to the further reading list for more details.

The sensing of chemicals: Chemicals are essential to our everyday life. Biological nanopores are also proven to be capable for the detection of the chemicals after connector modifications.

Presently, the chemical detection is mainly based on the physical blocking of current signals when chemicals interact with the functional groups in the connector. The detection of chemicals with modified bacteriophage connector has been reported. By mutating the lysine-234 to cysteine in the phi29 nanopore, the modified phi29 nanopore can distinguish among ethane, thymine, and benzene with thioester moieties. The binding events between the connector and chemicals can cause current blockage events. The unique electric signals are generated by the physical blockings when the chemicals react with the cysteine residues on the connector during the translocation process. From the analysis of the binding events among ethane, thymine, and benzene, the current blockage for the permanent binding events have been found to allow for the discrimination among the three chemicals (Table 1).

The biological nanopore sensing of peptides and proteins: Polypeptides or proteins play significant roles in biological functioning. Even though the nanopore-based sensing of proteins or peptides is still a nascent technology, it presently can achieve the detection of the proteins or peptides at the single-molecule level.

In the single pore sensing of polypeptides, the short peptides have the possibility to translocate through the nanopore channel to produce current blockage. However, due to the relatively small size of the nanopore, larger sized polypeptides or proteins cannot be translocated. In this situation, a current blockage may occur through nanopore conformational changes caused by specific interactions between the larger-sized proteins and the connector. Therefore, the dwell time indicates either the time required for one complete translocation event or the interaction time between the nanopore and the analytes. As mentioned earlier, as peptides are driven to be translocated or to interact with the connector by electrical force, the intrinsic properties of the polypeptide such as length and charge, type and modification of the connector greatly influence the current blockage and dwell time. Researchers have been able to discriminate peptides with different compositions and lengths from the nanopore technique experimentally. For example, Fig. 7 shows the differences in the current signatures to discriminate peptides with same lengths but different compositions. Ji and coworkers were also able to differentiate among peptides with different numbers of arginine residues using T7 nanopore technology. Fig. 8 compares the current blockage and dwell time to distinguish peptides with the number of arginine residues ranging from 8 to 12. Like other biomolecules, longer peptides generated larger current blockage and longer dwell time. Moreover, the peptides with same length and composition can also be detected using the peptide digestion assay. The main idea for the detection is that peptides with various lengths will be created after specific enzyme digestion. Furthermore, the phi29 connector was inserted into the stable polymer membrane in Oxford MinION flow cell, which

Table 1 Comparison of permanent current blockage events among thioesters

<i>Thioesters: Permanent Binding Events</i>					
<i>Transient binding events</i>		<i>Permanent binding events</i>		<i>Ratio of permanent to transient events</i>	
<i>thioesters</i>	<i>(Cys-X)</i>	<i>(Cys-X + Cys-X)</i>	<i>p value</i>	<i>(Cys-X + Cys-X)/(Cys-X)</i>	<i>p value</i>
ethane	16.4 $\pm$ 2.0%	33.5 $\pm$ 0.5% (N = 63)	<0.001 (thymine); <0.001 (benzene)	2.04 $\pm$ 0.12	<0.001 (thymine); <0.065 (benzene)
thymine	18.9 $\pm$ 2.6%	36.3 $\pm$ 1.2% (N = 44)	<0.001 (ethane); <0.001 (benzene)	1.92 $\pm$ 0.14	<0.001 (ethane); <0.437 (benzene)
benzene	19.5 $\pm$ 6.2%	38.4 $\pm$ 2.0% (N = 66)	<0.001 (ethane); <0.001 (thymine)	1.96 $\pm$ 0.32	<0.065 (ethane); <0.437 (thymine)

comprises 2048 wells in the portable MinION device for high-throughput peptides sensing. Currently, the TAT, R14, MAR, and P27 peptides were found to be able to generate distinct current blockages signals in the MinION. This innovation has greatly advanced the development in peptides sensing and sequencing. Please refer to the further reading list for more details on the peptides sensing.

Scientists have also developed methods to detect proteins that are too large to pass through a nanopore via the analysis of fingerprinting signals by specific protein-nanopore interactions. For example, Wang and coworkers (Please refer to the further reading list for more details) incorporated an Epithelial Cell Adhesion Molecule (EpCAM) peptide into the C-terminal of phi29 connector channel to

detect the EpCAM antibody. Upon the specific interaction between the EpCAM peptide and the antibody, it was possible to collect distinct current blockage signals from the background even though many other nonspecific antibody or serum components were present.

Summary

The phage dsDNA-packaging motors have long been thought to be rotation motors. A third type of biomotors recently has been discovered that translocate dsDNA by a revolution mechanism without rotation, and are commonly found in viruses, bacteria, and eukaryotic cells. Analogously, the rotation motion resembles Earth rotating on its own axis every 24 h, but revolution resembles Earth revolving around Sun every 365 days. The revolving motion renders a motor free of friction, coiling, and torque, which has helped clear up many puzzles of viral DNA packaging motor studies over the structure, stoichiometry, and functioning of DNA translocation motors.

In recent years, development and application of biological nanopores have advanced significantly. These biological nanopores can detect different types of molecules, such as DNAs, chemicals, and peptides. The bacteriophage nanopore has proven its ability for discriminating DNAs with a variety of lengths and conformations. These studies indicate likelihood of future applications of the bacteriophage conduits in detection of biomarkers, such as miRNAs, which can be achieved by the conformational differences in the absence and presence of target analytes. Regarding chemical sensing, specific modifications on the nanopore channel can generate unique signals for individual chemicals. Additionally, the biological nanopores can distinguish among short peptides. The analysis of the product peptides with the use of enzymes also shows the evidence of the nanopore system to differentiate among proteins of similar sizes. This differentiation further indicates the potential to detect specific enzymes by the nanopore system. Overall, based on their ability to provide quantitative analyses of molecules of many kinds, nanopores have great potential for disease diagnosis.

The biological nanopores can be used in versatile applications, though several challenges remain. The type and number of analytes that can be discriminated by single pore sensing are inadequate. Different analyte detection will likely require the relevant modification of the nano-channel with distinct properties and specifically designed probes. For example, the detection of certain

chemicals may require the specific types and modifications of the nanopore for specific binding between the analytes and the connector. In addition, the detection or sequencing of proteins remains challenging. Further studies are necessary to build the database for peptide discrimination or sequencing. Moreover, to transfer the nanopore sensing technique to the clinical trials, additional knowledge on how to enhance the sensitivity and specificity in clinical samples or in the presence of many impurities are necessary to be revealed. In sum, the single pore sensing is becoming a powerful analytical tool, but still requires further improvement and exploration of various connectors.

General Ecology of Bacteriophages

Stephen T Abedon, The Ohio State University, Mansfield, OH, United States

© 2021 Elsevier Ltd. All rights reserved.

Glossary

Burst Release of phages from a bacterium, usually upon lysis. Burst size is the number of phage virions released per phage-infected bacterium.

Chronic release The continuous release of phage progeny from infected bacteria in a manner that does not involve bacterial death, infection loss, or host lysis.

Epifluorescent microscopy Microscopic observation of light absorbed and then reemitted from specimen-bound dyes.

Fecundity Measure of the number of offspring produced by an individual.

Latent period The time beginning with phage adsorption to a bacterium and ending with phage release from a bacterium.

Metagenomics The isolation and sequencing of genomic nucleic acid from whole communities including bacteriophage communities such as those found within a sample volume of seawater.

Plaque Localized region of phage population growth occurring in association with a turbid, spatially constrained bacterial population (bacterial lawn), as resulting in localized clearing of that turbidity.

Pseudolysogeny A latent phage infection in which penetration of the phage genome into the bacterial cytoplasm has occurred but subsequent steps towards either productive infection or lysogeny are delayed.

Pseudolysogeny is thought to occur primarily when bacteria that are in a significantly starved state are infected by a phage.

Single-step growth A technique involving adsorption of phages to bacteria that is followed by a determination of the timing of phage-progeny release from the now-infected bacteria, as well as determination of the total number of phages released per bacterium. The word 'single' (or 'one') is used to indicate that the released phages are prevented from infecting or even adsorbing to subsequent bacteria found within the experimental vessel.

Spatial structure Environmental impediments to mixing, diffusion, and organism motility such that the present spatial position of an organism serves as a good predictor of future spatial position. In the microbiology laboratory, spatial structure is often imposed upon cultures via the addition of agar to growth media, e.g., such as may be found within a Petri dish.

Introduction

Bacteriophages are viruses of bacteria. An enormous number of bacteriophages are found the world over, on the order of 10^{30} or more. By way of comparison, 10^{30} is approximately the weight of the Sun, in pounds. This article presents an overview of the interactions between bacterial viruses and their environments: that is, an overview of phage ecology. Phage ecology is an exploration of how bacteriophages exist in the wild, and of their impact there.

Phage Existence Within Environments

Phage populations have been documented in more or less all environments within which bacteria have been documented. Phage ecological characterization begins with efforts to determine what phages are present within specific environments and in what numbers. With the availability of modern molecular, microscopic, flow-cytometric, and sequencing techniques, it is relatively easy to obtain direct counts or to molecularly characterize uncultured phage virions obtained from environmental samples. A variety of techniques may also be employed to study viral infection/production (aka, proliferation) within environments, though none of these methods are ideal. Estimations of lysogeny in environments are possible but similarly are not ideal.

Overview

Determination of phage numbers by viable count, typically meaning plaque count (Fig. 1), once dominated phage environmental endeavors, particularly prior to the 1990s. Direct microscopic counts, however, are generally much higher than viable counts, for example by as much as 10,000-fold. For isolation of viable phages from environmental samples, selective enrichment techniques are often employed. Representative phage numbers, but more generally *virus* numbers determined by direct counts range from 1×10^4 to 2×10^7 per ml of seawater. Assuming virion degradation between sampling and enumeration in the above estimations, these numbers are calculated to be as high as, e.g., $3\text{--}100 \times 10^6$ per ml. Sediment and terrestrial virus counts can be even higher than numbers as found in open water.

Especially using epifluorescence microscopy, phage direct counts are accomplished more easily than either phenotypically characterizing environmental phages or demonstrating phage environmental impact on specific bacteria. Various molecular

Fig. 1 Bacteriophage plaques. Shown are two strains of phage T4 as grown on the host bacterium, *Escherichia coli*. The larger plaques are made by an *r* mutant, which can display a significantly shorter latent period than the smaller-plaques wild type. Note the abruptness of the ‘collisions’ between *r*-type and wild-type plaques, which is suggestive that phage infections likely extend here beyond the visible portion of the wild-type plaques, an interesting laboratory-ecological phenomenon which was first observed in the late 1940s.

approaches – including pulsed-field gel electrophoresis and metagenomic sequencing of phage environmental populations – allow characterization of phage environmental diversity, especially in terms of genotype. While electron microscopy of environmental samples does allow some phenotypic characterization, particularly of virion morphology, none of these approaches are substitutes for phenotypic analysis of individual phage isolates found in at least ‘phage’ pure cultures. In most cases, however, such characterization is not easily accomplished because the majority of presumptive phage hosts are not easily cultured in the laboratory. Phage culturing and microscopy are considered in greater details as follows.

Phage Isolation and Host Range

Phage presence as well as host range diversity can be assessed by determining phage viable counts. Typically this involves plaquing (Fig. 1). Though rarely employed, it is also possible to dilute phages suspended in liquid such that their isolation and even enumeration, using the most probable number method, can be achieved without plaquing. While directly plating environmental samples can be desirable, phage densities are not always sufficient for either isolation or quantification. Two general approaches exist for increasing phage numbers associated with environmental samples: selective phage enrichment and phage concentration. Selective enrichment involves incubating an environmental sample in liquid culture supplemented with a specific bacterial host. The result is a selective increase in the number of those phages which are able to productively infect that host. Concentration of environmental phages requires more sophisticated techniques and equipment, such as filtration, high-speed centrifugation, or precipitation, but allows quantitative determinations of even low environmental densities of phages. Unfortunately, all handling steps involved in phage isolation are likely to result in enrichment of phages possessing certain properties, such as phages which replicate more effectively under enrichment conditions, which have virions that are better able to resist physical damage, or which produce more-easily noticed plaques.

Even when carefully employed, viable counts, as noted, tend to grossly underestimate total phage numbers. Aside from phage losses due to handling, these underestimations can stem from the relatively narrow host ranges of phages that allow only a small portion of a phage community to infect or form plaques on a given bacterial host. Also, it is uncertain what fraction of total phage virions are viable under even ideal laboratory conditions nor how much laboratory environments deviate from each phage’s ideal growth environment. Furthermore, also as noted, not all bacteria are culturable; in fact, the vast majority of bacterial species currently are either nonculturable or, at least, difficult to culture using standard laboratory procedures. The resulting limitations on testing phage samples against most hosts necessarily limit our understanding of phage host range diversity within environments.

Microscopic Determination

Historically, microscopic determinations have played important roles in the study of phage environmental microbiology, since it was through these observations, especially in the late 1980s and early 1990s, that aquatic environments were found to harbor vast numbers of virus-like particles, especially phages. These observations made it obvious that phage-bacterial interactions could occur within environments with great regularity, suggesting that phages could enormously impact aquatic bacteria.

Early visualization of phages involved almost exclusively electron microscopes, since the small size of phages causes them to appear, at best, as pinpricks of light using dark-field optical microscopy. Furthermore, electron microscopes allow scrutiny of phage morphology, which is helpful in differentiating virus-like particles from non-virus particles of similar size, and in obtaining a first approximation of virion *in situ* diversity. Unfortunately, electron microscopy is fallible because viruses that are not obviously (or exclusively) virus-like in their morphologies are less likely to be enumerated, and thereby may be excluded from viral total

Table 1 Common metrics of phage ecological, and universal, abundance

Measure	Quantity
Approximate number of phage hosts worldwide	10^{30}
Typical ratio of phage to bacteria in environments	10:1
Approximate average phage density in sea water	10^7 ml^{-1}
Typical range of phage densities in aquatic environments	$10^4\text{--}10^8 \text{ ml}^{-1}$
Approximate phage density in soils	10^8 g^{-1}
Approximate phage density in sediments	10^{10} ml^{-1}
Total volume of phage habitats (mostly ocean)	$> 10^{24} \text{ ml}$
Estimated worldwide number of virus particles ^a	10^{31}
Estimated total phage mass assuming 10^8 Da/virion	10^{15} g
Approximate phage mass in 'blue-whale units' (BWUs = 10^8 g)	10^7 BWUs
Cumulative length of phage particles lain end to end	10^8 light years

^aIt is typically assumed that most virus particles observed in the wild are phages.

counts. An additional problem with total counts is that they can determine neither the viability nor the host range of the observed viruses. This includes uncertainty about what fraction of the observed viruses are indeed phages as it is especially difficult to distinguish tailless phages from various groups of eukaryotic viruses. For this reason, researchers who use culture-independent microscopic techniques tend to classify all observations as 'viruses-like particles' and not necessarily as 'phages'. Because of virion morphology and the relative prevalence of bacterial hosts in environments, it is assumed that the majority of observed virions in most environments never the less are phages.

Alternatively for determining virion total counts is epifluorescence microscopy, a technique requiring less-sophisticated equipment and sample preparation than electron microscopy. In epifluorescence, virus-containing samples are stained with nucleic acid-binding fluorescent dyes that allow viruses to be viewed using a fluorescent microscope (again as pinpricks of light, though now pinpricks of illuminated viral genomes). Both electron microscopy and epifluorescence microscopy, like viable counts, often require sample concentrating prior to enumeration. In general, electron microscopy allows determination of virion morphologies while epifluorescence allows differentiation of entities containing nucleic acid from those lacking it.

As these various forms of microscopy and sample preparation have been refined and developed over the past 30 or so years, more accurate determinations of environmental phage numbers have become possible, and estimates of $\sim 10^6$ or more phages per milliliter are typical in pelagic aquatic environments (i.e., within water columns). In marine environments, phage densities appear to be greater in coastal waters (e.g., $\sim 10^7 \text{ ml}^{-1}$ or more) versus more off-shore waters (e.g., $\sim 10^6 \text{ ml}^{-1}$ or more). Densities may be in ranges closer to $\sim 10^8 \text{ g}^{-1}$ for terrestrial environments (i.e., soils) as well as productive lakes and even higher still (up to 10^{10} g^{-1}) in sediments, though note that in general study of the ecology of viruses in soils, or sediments, is more difficult than its study in more fluid environments. Although densities tend to decline in deeper sediments, it is speculated that shallow sediments could serve as reservoirs for pelagic viruses, offering long-term, perhaps many decades, phage storage such that sediment disruption may return phages to overlying waters, serving to a degree as equivalents to plant soil 'seed banks'. Using these methods, it has been estimated that at least 10^{30} phage particles, and perhaps as many as 10^{31} or more, are present on the planet at any given time, where the lower figure is equal to approximately the volume of all the world's oceans, in milliliters, times 10^6 (Table 1).

Phage Ecology

The science of ecology may be differentiated into a number of more-or-less distinct subdivisions. These include organismal, population, community, ecosystem, and landscape ecologies. Also included, especially under the heading of organismal ecology, are physiological and evolutionary ecologies. Though important to an understanding of ecology in general, in most cases little effort is made within the phage ecology literature to explicitly distinguish among these various categories, plus there exist numerous overlaps between categories. Indeed, phage biologists including this author often are trained first as microbiologists, or as molecular geneticists, etc., and only later or much less so as ecologists. As a consequence, phage publications relevant to our understanding of phage ecology typically will not describe their contents from a classically ecological perspective. A major goal of this section, therefore, will be to expose readers to phage ecological thinking as organized within a more general ecological framework, presented in overview as follows.

Overview

What can be described as a phage *organismal ecology* considers phage adaptations within environments, with emphasis on phage survival, reproduction, and dissemination. Included under this heading can be phage physiological ecology, which considers the impact of environments on phenotypes. For phages this would be manifest either through modifications in the physiology of bacterial hosts or in terms of environmental impact on virion properties. Also included under the heading of phage organismal

Fig. 2 Lytic bacteriophage life history. Images © James A. Sullivan, used with permission.

ecology is phage evolutionary ecology, which considers the selective benefits of phage adaptations, i.e., how adaptations impact phage evolutionary fitness (survival and growth rates).

Phage *population ecology* considers phage intraspecific interactions, particularly in terms of how those interactions control phage population size, dispersion, and growth rates. Phage *community ecology* considers phage interactions with other species, especially with bacteria but also with other types of phages. Also are the biotic components of the greater bacterial environment, such as in terms of the impact of phage-encoded exotoxins on the eukaryotic hosts of bacteria. Phage *ecosystem ecology* considers phage impact on nutrient cycling and energy flow within ecosystems, which by necessity represents a much more abiotic emphasis than other approaches. Phage *landscape ecology*, which has not been substantially considered explicitly within the phage literature, would consider the phage impact on interactions between distinct ecosystems, such as between a pond and a surrounding forest, a sewage treatment plant and downstream environments, or an animal (serving as an ecosystem itself) and the extra-animal environment.

Note that these various means of looking at phage ecology build upon one another. That is, ecosystem ecology builds upon community ecology which builds upon population ecology which builds upon organismal ecology which, finally, is understood best in light of a strong molecular appreciation of phage biology.

Phage Organismal Ecology

Phage organismal ecology may be considered from the perspective of environmental impacts on phage 'growth' parameters, particularly as affecting phage reproduction, dissemination, and survival. More specifically are such things as phage adsorption rates, infection timing, productive-infection versus lysogeny decisions, burst sizes, and virion decay rates. Since our understanding of phage growth parameters is derived from the laboratory characterization of phages, this section describes this aspect of phage ecology by employing a very much laboratory-centered emphasis.

The traditional means of studying most phage growth parameters are single-step growth experiments and phage adsorption determinations. We can fit these growth parameters into a generalized scheme of the phage life cycle, and then consider how variation in the assorted steps of this life cycle can impact phage ecological success. These steps, in order, include (**Fig. 2**) (1) a diffusion-driven phage-virion extracellular search for bacteria to infect, (2) the phage adsorption process during which a relatively inert phage-virion and adsorption-susceptible bacterium are together converted into a phage-infected bacterium, (3) the phage infection which can vary in its phenotypic expression from restricted (phage dies, bacterium lives) to abortive (both phage and bacterium die) to productive (phage lives but bacterium dies) to pseudolysogenic (or 'carrier state'; especially, a relatively unstable latent infection) to lysogenic (a somewhat stable latent infection), and (4) some means of phage-virion release into the extracellular environment. The latter, depending on the phage, may or may not involve host-cell and infection death (i.e., via lysis versus chronic/continuous release, respectively).

Consideration of how variation in these assorted steps can impact phage ecological success is presented in the following sections. For example, we can expect rapid virion adsorption – particularly rapid phage attachment given encounter with a phage-susceptible bacterium – to be favored over less-rapid adsorption unless phenotypes conferring rapid adsorption interfere with phage survival or fecundity. For instance, T4-like phages may enhance their survival within extra-colonic environments by taking on a temporarily adsorption-incompetent but inactivation-resistant state. Another counter to the evolution of more-rapid phage adsorption/attachment may be phage growth within relatively spatially structured environments, if there exist tradeoffs between time spent disseminating versus time spent infecting bacteria. Note that these considerations of phage adsorption rates more generally reflect differences between phage properties 'as virions' versus 'as during bacterial infection', differences which are explored more fully in the following section.

Phage infections in the wild also can be less efficient than those studied under laboratory 'ideal' conditions for phage growth (e.g., smaller burst size, longer latent period, slower adsorption). The major bacterial nutrients, carbon and energy, as well as critical minerals, such as phosphorus, can be in short supply within many environments, resulting in such inefficiencies in nature. The ecological study of organismal physiological response to changing environmental conditions is termed physiological ecology, or ecophysiology in short. In addition to developing a better general understanding of phage *in situ* population ecology,

consideration of phage ecophysiology is relevant to estimating levels of phage-induced bacterial mortality within natural environments, an important aspect of *in situ* phage–bacterial community ecology.

Bacteria-like versus virion-emphasizing modes of existence

The selective advantage associated with various phage infection and release strategies, similar to phage adsorption rates, will be dependent on environmental conditions, particularly in terms of numbers of bacteria, bacterial physiology, and rates of phage decay. In general we can assume that conditions that favor bacterial growth and survival over phage population growth and survival will tend to favor more bacteria-like modes of phage replication/survival over more production of phage virions-emphasizing modes; more precisely, we can expect life history biases towards phage existence infecting a bacterium rather than towards greater emphasis on existence as free virions. Thus, low bacterial densities, bacterial physiologies that poorly support significant virion production, or virion-specific environmental antagonists including phage-restricting bacteria will tend to favor extended phage latent periods. These infecting states may include pseudolysogeny, lysogeny, or productive but longer-lasting infections, including infections by phages that release their progeny chronically rather than lytically. Alternatively, we can assume that conditions that favor phage population growth will tend to favor more productive modes of replication, that is, ones that emphasize the virion state over the infected state. This more virion-emphasizing state can include shorter-lengthed productive phage infections – especially lytic infections that favor earlier virion release over higher infection fecundity – but also more-rapid chronic virion release at the expense of longer-term infection survival.

The advantage of displaying a more virion-emphasizing existence may be viewed from two perspectives. The first are conditions that allow for rapid phage-population expansion, i.e., relatively high densities of uninfected host bacteria. Less intuitively, that expansion comes at the expense of bacterial survival, and therefore any phage which persists within a more bacteria-like (extended latent period) mode of infection may be more susceptible to attack by unrelated phages under conditions which are favorable toward phage population expansion (see, e.g., ‘Killing the winner’, below). Also favoring the virion over the infecting state, a temperate phage can increase its target number and reduce its genomic target size via lysogen induction, i.e., by changing from a single bacterial lysogen to multiple copies of phage virions. Such induction can occur following bacterial lysogen exposure to DNA damaging agents. In considering phage population growth and survival, we thus can envisage phage adaptation as involving compromises between conflicting tendencies toward greater emphasis on existence as an infection versus greater emphasis on existence as a virion.

Phage Population Ecology

Considerations of phage population ecology may be differentiated into two categories: (1) the impact of phage adaptations and environmental conditions on phage population growth within well-mixed, fluid environments (such as within broth in the laboratory) and (2) the impact of phage adaptations and environmental conditions on phage population growth within spatially structured environments (such as within soft-agar overlays in the laboratory; [Fig. 1](#)). These categories will be considered in turn. Like phage organismal ecology, much of our understanding of phage population ecology derives from laboratory characterization of phages, but also from exercises in mathematical modeling of phage population growth. We can also distinguish phage population considerations into those operating at low phage densities versus those operating at high phage densities. In both cases density refers to that of a single phage population since inter- as opposed to intra-species interactions are considered under the province of phage community rather than phage population ecology. These latter considerations are much simpler to envisage during phage broth-culture growth.

The growth of phages in broth can be considered to occur over at least four distinct steps. These are as follows:

- (1) Phage entrance into an environment. This can be physical, in terms of phage movement from one place to another, physiological in terms of the induction of an already-present lysogen, or genetical in terms of phage host-range mutation such that a previously phage-insusceptible bacterial population suddenly becomes susceptible to sympatric phages.
- (2) A period of phage-population growth that spans from the point of the initial phage infection of a susceptible bacterium within an environment through to the point of transition where most susceptible bacteria have become phage infected. Most bacteria will become phage infected, however, only if sufficient bacteria are present to support phage population growth to relatively high densities.
- (3) The transition to and then span over which most of the phage-susceptible bacteria within a population have become phage infected.
- (4) A postinfection, particularly post community-wide bacterial lysis period during which phage numbers greatly outnumber those of bacteria.

In many cases, each of these steps is at best a transient phenomenon for a given combination of phage, bacterium, and environment.

Once a phage virion has been released from an infected bacterium, it has entered into a period of what can be described as an extracellular search for new bacteria to infect. The duration of this search will be a function of the product of the density of phage susceptible bacteria within a given environment – which in turn can be a function of the range of bacterial types that a given phage may infect – and the phage adsorption rate constant, which will vary as a function of phage, bacterium, and environmental parameters. The likelihood that a given phage will successfully adsorb to and infect some bacterium is additionally a function of a phage’s decay rate, a.k.a., virion inactivation rate, with higher decay rates reducing the likelihood of successful infection by a virion. Decay can be a function of abiotic insults that result in virion capsid or nucleic acid damage, phage adsorption to abiotic materials,

biotic insults including engulfment by eukaryotes as well as inactivation mediated by phage-adsorbed bacteria, or, from a modeling perspective, even emigration out of an environment. To a phage entering a previously phage-free environment, the likelihood that phage population growth will occur therefore is a function of bacterial numbers, rates of phage adsorption per bacterium, and rates of phage decay.

If successful adsorption occurs, then the likelihood that phage population growth will continue beyond this first adsorption will be a function of phage burst size, with each additional phage produced per infection potentially possessing an additional, nearly identical likelihood of subsequent successful bacterial adsorption. Extending this point, we can assume that with either higher bacterial numbers, more-effective/rapid virion adsorption per bacterium, lower rates of decay, or higher initial virion numbers, then there will be a greater likelihood that phage population growth will be initiated upon phage entrance into a new environment. Overall the potential for a phage population to grow within a given environment can be described as its existence conditions.

Once phage population growth has begun, it seems unlikely that there would exist any intrinsic inhibitions on phage evolution toward faster population growth. Both in terms of intraspecific and inter-specific competition among phages, it is that phage which reaches a bacterium first that should have the greatest potential to 'claim' that bacterium for infection. Thus, a phage type that grows its population fastest will have access to more bacteria sooner, and therefore enjoy among its progeny greater overall numbers of bacterial infections within a given environment. In general, we can expect faster overall phage population growth given greater phage burst sizes, shorter phage latent periods, or faster phage adsorption. Phage decay can also affect rates of phage population growth, and this occurs via reductions in effective phage burst sizes, where the qualifier 'effective' refers to the number of phages released from a given bacterial cell which go on to successfully infect new bacteria.

Things change, within a given environment, as a phage population reaches the limits of its population growth. At this point the selective pressures on phage growth change from ones that are mostly phage-density independent to ones which instead are highly phage-density dependent. These phage-density-dependent limits vary in their relevance, however, depending on bacterial densities along with phage fecundities. At one extreme, bacterial densities are so low, or phage fecundities (effective burst sizes) so small, that phage populations never reach densities of sufficient size to greatly affect bacterial populations. Under these conditions, multiple phage adsorptions to a given bacterium is of low likelihood and competition between phages for individual bacteria small. Selection here should be biased toward greater virion or infection durability, for example, rather than higher rates of phage population growth. We have this expectation because bacterial rarity presumably would put a premium on phage survival prior to bacterium encounter and also because phage potential to migrate to new bacteria-containing environments could be a function of longer-term phage survival, either as virions or as bacterial infections.

At the other extreme, bacterial densities as well as phage fecundities may be sufficiently high that a majority of phage-susceptible bacteria may become phage infected and therefore no longer available for further infection by the same phage type. Prior to this point we may expect selection to favor phages that display rapid population growth, even if such rapidity should come at the expense of effective burst size, such as in terms of actual burst size or in terms of virion resistance to decay. Thus, at higher bacterial densities, while phage densities are still relatively low, a phage could display faster population growth by shortening its latent period. Such shortening, however, is most easily accomplished at the expense of the overall duration of the period during which phage progeny intracellularly mature, resulting in a reduced phage burst size. Alternatively, one could envisage a loss of phage genes that otherwise could contribute to long-term virion survival should the presence of those genes come at the expense of effective phage burst size or further latent period shortening. One possible example of such evolution could be a common loss of abilities to display lysogenic cycles among phages contaminating industrial dairy ferments.

Adaptation that results in declines in phage survival could be shortsighted within environments in which densities of new bacteria to infect come to rapidly decline. Instead, we can envisage an advantage bestowed upon phage infections during 'final rounds' of infection – that is, at the point where most bacteria within a population have become phage infected – that would result from larger effective burst sizes. In this way more or more robust phages are produced to better assure phage survival until access to a new bacterial population occurs. Somewhat equivalently, a phage may accrue advantages by displaying more bacteria-like lifestyle under conditions where bacterial densities are in decline, such as via temperate-phage reduction to lysogeny upon bacterial adsorption rather than display of a lytic infection (above).

Many of these same effects take place during phage population growth within spatially structured environments, such as within bacterial lawns immobilized within soft agar, that is, as phage plaques (Fig. 1) or, as we can speculate, in association with bacterial biofilms. A difference, though, is that in addition to temporal differentiation between phage density-independent and phage density-dependent selection, there also can be spatial differences. Thus, phage multiplicity may be higher toward the center of plaques versus toward their periphery. In other words, at a plaque's leading edge, selection acting upon phage characteristics likely is more phage density independent than toward the center of plaques. Therefore, we can expect selection for faster phage population growth to occur at a plaque's periphery, whereas, by contrast, selection at a plaque's center should be biased more toward a greater effective burst size. As noted, it may be possible to extrapolate, to a degree, the characteristics of phage population growth within phage plaques to that in association with at least some bacterial biofilms.

Phage Community Ecology

Phage community ecology includes issues of phage predation on bacteria as well as the establishment of mutualistic-like relationships such as those between prophages and bacteria, forming lysogens. The phage community ecology literature is more

closely aligned with the ecological literature, which is to say that a good deal of phage community ecology has been done by individuals trained first as ecologists who have then taken to phages as model systems rather than by individuals trained first by studying more organismal or more molecular aspects of phage biology. As such, phage community ecology has a much more theoretical basis than either phage organismal or population biologies, including the employment of simulations of phage-bacterial interactions, especially within continuous cultures (chemostats). In addition to considerations of phage impact on bacterial populations, including as can be associated with other organisms such as ourselves, phage community ecology can also consider interactions between different phage species or grazing on phages by protists.

We can distill three general governing principles of phage community ecology, especially with regard to phage impact on bacteria: (1) The greater a phage population density then, all else held constant, the greater the phage impact on a bacterial population, and the faster that phage populations reach these higher densities, then the sooner their impact. (2) The greater the density of phage-sensitive bacteria, then – potential changes in bacterial physiology aside – the greater the population size that phages can reach and the sooner they will grow to those population sizes. And (3) Bacteria can hide in various ways from phages – numerically, genetically, phenotypically, physiologically, spatially – but doing so can come at a cost in terms of, for example, bacterial growth rates.

Real world applications of these concepts include that of ‘Killing the winner’ where it is expected that populations of same or similar bacterial types, which grow to higher densities, will tend to become more susceptible to phage-mediated population crashes. These crashes result solely from bacteria having reached these higher densities and thereby being able to support phage population growth to higher densities. By culling especially more successful bacterial populations, phages may serve as mediators of a frequency-dependent selection among bacterial communities that results in greater bacterial diversity than environments might otherwise sustain.

A second and related real-world consideration is that bacteria within especially eutrophic, i.e., high-nutrient environments, where phage virions can be especially abundant, may display physiologies that represent tradeoffs between rates of bacterial growth and phage-free survival. That is, bacteria may be subject to physiological and other burdens that come with deploying protective measures against potentially infecting phages. Protective measures are diverse and include such things as restriction-modification systems along with CRISPR-Cas systems. Additionally, bacteria may take on more-protective lifestyles, potentially such as within extracellular polysaccharides as found in association with biofilms.

Bacteria may also display reduced versatility in the course of mutating to phage resistance because of loss (temporarily or permanently; fully or partially) of membrane proteins involved, for example, in nutrient transport, proteins which could otherwise serve as phage receptors. That is, the more proteins or other molecules a bacterium displays on its surface, then the more phage types that bacterium may be susceptible to. Because many of these mechanisms of phage resistance can result in reduced bacterial fitness, we should expect that the strength of selection for phage resistance should be directly proportional to phage density within a given environment. Phages, in turn, can display adaptations which allow them to overcome various bacterium-mediated mechanisms of phage resistance. Bacteria can also evolve to mitigate the costs associated with displaying phage resistance.

A third real-world consequence of phage impact on bacteria can result from phage-mediated transduction of bacterial genetic material. Phages do this by two basic mechanisms: generalized transduction in which random pieces of bacterial DNA are incorporated into consequently defective phage virions, and specialized transduction. The latter traditionally involves the incorporation of that bacterial genomic DNA which flanks bacterial-chromosome inserted prophages, and occurs as a consequence of imprecise prophage excision upon induction. Serving essentially as an extension of the concept of specialization transduction is phage encoding of ‘morons’, which involves the incorporation via illegitimate recombination of bacterial genes into various locations within temperate phage genomes. This ‘more DNA’ is then passed on to bacteria in the course of establishment of lysogeny by moron-carrying phages. These genes, along with prophages generally, can impact bacterial phenotype including the fitness of lysogens, potentially positively. These latter mechanisms of transduction serve as a means of transferring genetic material from bacterium to bacterium while also transferring genetic material from bacterium to phage.

Phage Ecosystem Ecology

The primary emphasis of phage ecosystem ecology is on the impact of phage infection of prokaryotes on movement of nutrients and energy from prokaryotes to higher trophic levels. That is, phage infection influences the acquisition of bacteria including cyanobacteria by bacteria-eating eukaryotes. The real-world significance of this emphasis derives from prokaryotes serving as the base of many, especially aquatic ecosystems, and the role that these organisms play in carbon sequestration. That is, within aquatic environments most dissolved organic material becomes available to eukaryote grazers only once bacteria have assimilated it. With phage-induced bacterial lysis, however, a significant fraction, even 25% of the carbon entering these ecosystems photosynthetically, is converted to a dissolved organic state. This creates a ‘viral loop’ that shunts organic carbon away from what is known as the aquatic ‘microbial loop’, which otherwise moves carbon from prokaryotes to grazers, i.e., especially phagotrophic protists to grazer-consuming animals (Fig. 3). Another way of stating the significance of the phage impact on the survival of aquatic bacteria is that it is approximately equivalent to the impact of protist grazing. The impact of phage infection versus protist grazing, however, varies with habitat, with phages displaying a greater impact especially in more extreme, including low-oxygen environments.

Fig. 3 Microbial loop as short circuited by virus-, particularly phage-induced lysis. The viral loop consists of the generation of dissolved organic carbon via virus-induced lysis of especially heterotrophic bacteria and cyanobacteria (the latter here included under the heading, Algae), which is followed by assimilation of a fraction of that material into heterotrophic bacteria. The viral loop reduces the efficiencies by which photosynthetically fixed organic carbon is transferred to higher trophic levels via the microbial loop, such as to aquatic animals.

Glossary

Bathypelagic layer The *bathypelagic layer* extends from the mesopelagic layer to ~ 4000 m below the ocean surface, where the abyssopelagic zone begins. Because no light penetrates in the bathypelagic layer, it is also known as the dark zone.

Epipelagic layer The *epipelagic layer* represents the uppermost layer of the ocean, where sunlight easily penetrates and the photosynthetic autotrophs can be found. It extends from the 0 m to 150/200 m depth.

Fosmid Fosmids are cloning vectors based on the bacterial F-plasmid. They can hold DNA inserts of up to 40 kb in size.

Mesopelagic layer The *mesopelagic layer* represents the part of the pelagic zone in between the photic epipelagic and aphotic bathypelagic zones. It is also known as the twilight zone and it extends from ~ 150/200 m to ~ 1000 m depth. It begins at the depth where only 1% incident light reaches and ends where there is no light.

Nanopore Sequencing Technology Nanopore sequencing technology, as developed by Oxford Nanopore Technologies Inc, produces long reads. The read length usually averages 4 kb, but, with DNA preparations minimizing fragmenting, it can reach even 1 Mb. From here on we will refer to this technology as the *nanopore technology*. It involves several steps. First, the sequencing library is prepared by binding adapters to DNA fragments, while striving to keep the fragment length as high as possible. Then, the library is loaded on a flow cell, which contains more than one thousand protein nanopores set in an electrically resistant polymer membrane. By setting a voltage across the membrane, an ionic current is passed through the nanopore. The protein nanopores can capture single stranded DNA and pass it through. Each time a base passes

through a pore, the electric current is changed and recorded. For each pore, the base sequence of a single DNA fragment passing through it is inferred from the changes in the electrical current.

Read In nucleic acid sequencing, a *read* is defined as the base pair sequence corresponding to a single DNA fragment.

Sequencing by Synthesis Technology Sequencing by synthesis technology, as developed by Illumina Inc., produces short reads of 200–400 bps, in very high throughput. From here we will refer to this technology as the *Illumina technology*. It involves several steps, as follows. First, the sequencing library is prepared by fragmenting the DNA and binding adapters to both ends of the fragments. Then, the library is loaded on a flow cell, where DNA fragments bind randomly to its surface, one fragment at a single location. This is followed by solid-phase amplification, which creates up to 1000 identical copies of each single DNA fragment. All copies from one molecule are found in close proximity, creating a cluster with a diameter of 1 μm or less. In a sequencing flow cell, there are millions of such clusters per square centimeter. Further, in each sequencing cycle deoxynucleotide triphosphates (dNTP) which are fluorescently labeled are added. Because the fluorochrome acts as a terminator, only a single base binds to a DNA molecule per sequencing cycle. After the base incorporation, the fluorescent dyes are imaged and then cleaved away from the DNA molecules, to allow the next cycle of sequencing. Because sequence clusters have a defined spatial localization on the flow cell, the sequence of every single read can be inferred from the order of the fluorescent signals corresponding to the four bases (A, T, C, and G) at the respective location.

A Short Introduction in Marine Phages

In the late 80's it was recognized that, in marine environments, viruses outnumber microbial cells by an order of magnitude. In seawater, virus numbers range in between 10^4 to 10^8 per millimeter. In sediments, virus abundance is even higher, up to 10^9 per cubic centimeter. The majority of these viruses infect bacteria, and they are called bacteriophages, or phages. Phages shape the bacterial community structure through viral lysis and influence both host metabolism through the expression of auxiliary metabolic genes and host evolution through horizontal gene transfer. Furthermore, phages are responsible for the viral shunt, in which organic matter is hijacked by viral lysis from being transferred to higher food chain levels through grazing. Through their various roles, phages are major drivers of marine biogeochemical cycles.

Morphological Diversity of Marine Phages

Generally, phage morphological diversity is low. All phages have a capsid, which is a protein shell surrounding the nucleic acid. Phage capsids are either helical or icosahedral in shape (see [Figs. 1–3](#)). A variation of the icosahedral shape is the prolate capsid, resembling an elongated icosahedron (see [Fig. 1](#)). Helical capsids are known only for ssDNA phages. The icosahedral shape is the

Fig. 1 Phage capsid types.

Fig. 2 Morphological and taxonomic diversity of marine dsDNA phages.

Fig. 3 Morphological and taxonomic diversity of marine ssDNA phages.

most encountered, being present in all dsDNA and RNA phages and in part of the ssDNA phages. In rare instances, icosahedral phages are enveloped by a lipid layer. An additional structure, called tail, is present in the majority of known dsDNA phages. The tail mediates the adsorption to the host and the DNA transfer. There are three basic tail morphologies: podoviral, myoviral and siphoviral (see Fig. 2). In podoviruses, the tail is short and non-contractile. In myoviruses, the tail is long, rigid and contractile. In siphoviruses, the tail is long, flexible and non-contractile. Tailed phages have capsid proteins with an HK97 fold (named after the eponymous bacteriophage), while non-tailed phages have capsid proteins with a double jelly roll fold (DJR).

Because the majority of cultivated marine phages are tailed, and thus belong to *Caudovirales*, until recently it was believed that tailed phages dominate in the environment as well. However, it was shown by quantitative electron microscopy that non-tailed phages make up in between 66%–85% of environmental phages in global surface oceans. The identity and phylogenetic affiliation of these non-tailed phages is currently unknown. Part of them could be dsDNA phage with a DJR-fold capsid, from the *Corticoviridae* or “*Autolykiviridae*” families. Another part could be ssDNA phages from the *Microviridae* family. And another part most likely represents so far unknown phages.

As with their bacterial hosts, morphology alone cannot be used to classify phages or to predict their behavior and ecological role. Behind the few morphological types described, a huge genomic diversity is hidden.

Genomic Diversity of Marine Phages and How do we Study it

The marine phage diversity is large and just being explored. The methods used to study phage diversity fall within two categories: (1) culture-dependent methods, based on phage isolation in pure cultures and (2) culture-independent methods, based on microbial ecology tools, as for example sequencing of marker genes or of phage genomes directly from the environment. The first set of methods allows in-depth characterization of specific phage-host systems. For example, cultured phages can be visualized by electron microscopy, can be (relatively) easily genome sequenced, their interaction with the host can be studied in great detail and their host range can be determined. The second set of methods most often allows access only to phage gene or genome sequences. However, they allow sampling and analysis on a much larger scale than would be possible by using only phage isolates.

By now, phages for several marine bacterial groups have been isolated and characterized. For isolation of phage cultures from an environmental sample, the phage fraction of the respective samples has to be separated from the microbial cells first. Then, the phage fraction is mixed with growing cultures of the hosts of interest. The propagation of host-specific phages is monitored by tracking cell lysis, for example by plaque assays or turbidity measurements. If lysis is observed, the new phages are purified by successive plaque assays when the hosts can grow on solid media, or by dilution to extinction when the hosts grow only in liquid media. The most seminal isolation efforts were focused on phages infecting cyanobacteria, also called cyanophages. More than 7000 cyanophages have been obtained from different studies. However, many isolates have a high degree of genomic relatedness, which reduces their diversity to just a few groups. In comparison, the number of isolates available from other bacterial groups is smaller, but of comparable diversity. For example, to date there have been published 34 phages infecting the *Roseobacter* group, 40 phages infecting *Cellulophaga* and 15 phages infecting *Pelagibacter*. Although having phage cultures is highly advantageous, the inability to cultivate most of the marine bacteria results also in an inability to cultivate their phages and the diversity we see from cultured phages is only the tip of the iceberg. Therefore, researchers need other methods to access environmental phage diversity.

Phage Marker Genes

In microbial ecology, marker genes have long been used to analyze the composition and functions of microbial communities. The most used gene in diversity studies is the one encoding for the 16S rRNA, because it is universally present in cellular organisms and it is conserved, allowing identification and classification of microorganisms. In contrast, phages don't have a universally present gene. Instead, specific marker genes have been used to assess the diversity of certain phage groups in environmental studies. Genes encoding different proteins were used, as for example genes for the major capsid protein or the DNA polymerase. In these approaches, specific primers were used to amplify by Polymerase Chain Reaction (PCR) fragments of the marker genes, followed

by sequencing and sequence analysis. A recent development, the solid-phase single-molecule PCR polony method allows quantification of virus populations in nature.

Viral Metagenomics (Viromics)

Much of our knowledge regarding phage diversity comes from metagenomics studies. A metagenome represents a collection of the sequences of all DNA molecules in a sample. When only the viral fraction is targeted, it is named viral metagenome, or virome. To generate a virome, the phage fraction is separated, the DNA is extracted, fragmented in small pieces and sequenced using one of the high throughput sequencing technologies, most often Illumina. This approach generates many small sequence fragments, also called reads, which then have to be assembled into the original phage genomes (see Fig. 4). Most of the times, due to the huge sequence diversity, only partial phage genomes can be assembled. These partial or complete phage genomes (also called contigs) are then grouped into populations, roughly representing the equivalent of phage species, and then into viral clusters, representing approximately the equivalent of genera or subfamilies (see Fig. 5).

The biggest collection of marine viromes has been generated from three scientific expeditions through the world's oceans: Malaspina, Tara Oceans and Tara Oceans Polar Circle. A total of 145 samples have been collected, mainly from the epipelagic and mesopelagic layers, but also from the bathypelagic layer. The first analysis of these viromes included only the Malaspina and the Tara Ocean expeditions and only the epipelagic and the mesopelagic layers. The resulting dataset was labeled the Global Ocean Virome (GOV) and contained 1,380,834 viral contigs. These contigs were grouped first in 15,222 viral populations and then in 867 viral clusters. From the 867 viral clusters, two-thirds did not affiliate with any cultivated virus, underlining the richness of unexplored marine virus diversity. Five of the 867 viral clusters were relatively ubiquitous, being abundant in more than 20 samples. Only three of the clusters were related to known marine phage groups, that is the T4 superfamily, the Cbaphi381 virus, and the T7virus (see more about these groups in the "Cultivated marine phages" section). The predicted hosts for these viral clusters included *Actinobacteria*, *Alphaproteobacteria*, *Deltaproteobacteria*, *Gammaproteobacteria*, *Bacteroidetes*, *Cyanobacteria*, and *Deferribacteres*.

The second Global Ocean Virome (GOV2) dataset comprises all 145 samples, including the ones in GOV, deeper sequenced. In GOV2 there are of 195,728 viral populations with contig size bigger than 10 kb. From these, 90% could not be assigned to any known viral family, however, the expectation is that a big portion represents phages. The other 10% were assigned to dsDNA viruses and bacteriophages.

Standard viromics has enabled unprecedented access to the diversity of marine phages. However, one of its shortcomings is that microdiversity, defined by the presence in the same sample of similar phage genomes (for example genomes with >95% identity over at least 70% of their genome), hinders assembly of complete genomes from small reads. As a result, at least part of the phage contigs obtained from viromics studies originate probably from the phages with low microdiversity in the respective samples, but not necessarily with high abundances. Several approaches that can circumvent this problem are reviewed below.

Viral Contigs From Fosmid Libraries

A first approach is to clone environmental phage DNA into fosmids, and then to sequence each fosmid using Illumina technology (see Fig. 6). Because one fosmid carries only one phage DNA fragment, this reduces the assembly complexity and, in principle, allows the retrieval of phage contigs from microdiverse phages. On the other hand, large phage genomes cannot be cloned into fosmids, the practical insert size being in the range of 5–48 kb. Despite this limitation, complete phage genomes can be obtained using fosmid libraries, as exemplified by the retrieval of 208 such genomes from the deep chlorophyll maximum (DCM) in the Mediterranean Sea. These phage genomes were grouped in 21 clades of the *Caudovirales* and were predicted to infect SAR11, SAR116, *Cyanobacteria* and the low GC *Actinobacteria*. Fosmid libraries were also used to explore the viral diversity in the 1000 m deep Adriatic Sea and the 3000 m deep Ionian Sea. A total of 28 complete viral genomes, with lengths of 30–41 kb, were obtained. To assess the distribution of these genomes in the water column, raw reads from the Pacific Ocean virome dataset were mapped against each of them. From the 28 genomes, several were found only in the bathypelagic and mesopelagic layers and in high abundances. Five of the phage genomes were predicted to infect the deep ocean SAR11. From these five, uvDeep-CGR2-AD10-C281 was abundant in the mesopelagic and bathypelagic waters and uvDeep-CGR2-KM22-C255 was found both in the deep and surface waters. In addition, 11 contigs represented putative prophages likely infecting *Psychrobacter*, *Flavobacteria*, *Planctomyces*, and *Pelagibacter*.

Single Virus Genomics

A second approach is single-virus genomics. Individual phage particles are separated by flow cytometry, followed by genome extraction, amplification and then sequencing (see Fig. 7). The resulted genomes are called viral single-amplified genomes (vSAGs). Applying this method on seawater samples from the Mediterranean Sea and the Atlantic Ocean resulted in 44 vSAGs. Most of the vSAGs were tentatively assigned to the *Caudovirales*, representing potentially 37 new species and 7 new genera. One of the vSAGs, vSAG-37-F6, was later discovered to infect environmental *Pelagibacteriales* and was ranked as the 13th most abundant marine phage. Furthermore, a high abundance of vSAG-37-F6 transcripts was found in coastal temperate waters from the NE Atlantic, suggesting that this phage was actively infecting its host.

Fig. 4 Workflow for preparation of viral metagenomes.

A limitation of single virus genomics becomes visible when considering the high number of viral particles in environmental samples: this approach becomes impractical at the viral community scale.

Long Read Viromics

A third and very promising approach to capture phage microdiversity is VirION. It combines Illumina sequencing technology, with reads of ~ 300 bases, and nanopore technology, with reads of ~ 4000 bases. The combination is necessary because the long read technologies have a high error rate, and the high-quality Illumina reads are used to correct the errors. When applied to seawater

Fig. 5 Grouping of viral contigs in populations (based on sequence similarity) and clusters (based on shared gene content).

Fig. 6 Preparation of viral contigs from fosmid libraries.

samples from the Western English Channel, VirION was able to capture phage genomes belonging to abundant, microdiverse populations that were previously missed by short-read data. One of the assembled contigs, H_NODE_1248, was identified as the most abundant and ubiquitous viral genome in the marine environment. H_NODE_1248 belongs to the same viral cluster as 57 other contigs, including vSAG-37-F6.

Metagenome Assembled Viral Genomes (MAVGs)

Cellular metagenomes can be a rich source of phage contigs. It is estimated that in between 20%–60% of bacterial cells in the marine environment are infected by phages at any time. Therefore, bacterial metagenomes also contain sequences of phages actively infecting the cells at the time of sampling (see Fig. 8). The deeper the metagenome is sequenced (a higher number of reads

Fig. 7 Workflow for single-virus genomics.

produced), the higher the number of viral sequences retrieved. This approach was recently applied to samples from the Mediterranean Sea, from various depths and sampling sites. More than 1300 viral sequences were obtained, from which 36 contigs represented complete genomes. Host prediction indicated that part of the viral contigs infect *Cyanobacteria*, *Actinomarina*, SAR11, SAR116 or other *Alphaproteobacteria*. Most of the retrieved phage contigs were found exclusively in the Mediterranean Sea, and some were specific to the bathypelagic realm.

Linking Phage Genomes With Host Identity

Obtaining phage genomes using either viromics or single-virus genomics does not preserve the link between the phage and its host. Several computational methods can be used to predict the potential hosts, as for example (1) sequence similarity with known phages, (2) sequence similarity between phage and host genome, (3) similarities between phage genomes and host CRISPR spacers or (4) similarity of phage and host tRNA. However, for the vast majority of environmental phage genomes, the host cannot be predicted using bioinformatics approaches. Outside the realm of bioinformatics, phageFISH and viral tagging allow linking phage and host identity in environmental samples. In phageFISH, microbial cells in a sample are hybridized with fluorescently labeled probes targeting their 16S rRNA, for taxonomic identification. Simultaneously, intracellular phages are hybridized with probes specific for their genes, labeled with different fluorochromes. Hybridized cells and phages are detected by microscopy. Overlapping 16S rRNA and phage fluorescent signals are considered proof that those specific cells are infected by the targeted phage.

Another way to link phages and hosts is to sequence genomes from individual environmental cells. These type of genomes are called single amplified genomes (SAGs), because the DNA from one single cell is extracted and then amplified enzymatically to obtain the amount necessary for sequencing. Single cell genomics recovers all DNA molecules in a cell. Therefore, if infecting phages are found in the cell, they will be sequenced together with the genome of its host, enabling thus the linkage between host cell identity and phage identity (see Fig. 9). Even more, the approximate stage of infection can be estimated by comparing the number of reads per genome base, also called coverage, corresponding to the phage and bacterial genome. A higher coverage of the phage genome indicates a higher number of phages per cell, therefore an advanced infection stage. In SAGs obtained from the Saanich Inlet water column, 69 phage contigs infecting the gammaproteobacterial SUP05 clade were identified. Phylogenetic analysis grouped the contigs into five new genera within the dsDNA *Caudovirales* and the ssDNA *Microviridae*. Several cells were co-infected by dsDNA and ssDNA phages, potentially indicating a cooperative interaction

Fig. 8 Preparation of viral contigs from cellular metagenomes (MAVGs).

between these phage types. In another study, twenty complete or near-complete phage genomes were discovered in SAGs from seawater samples from the Gulf of Maine and the North Pacific subtropical gyre. The infected hosts belonged to *Marinimicrobia*, *Verrucomicrobia*, *Gammaproteobacteria* lineages SAR86 and SAR92, *Bacteroidetes* and *Alphaproteobacteria*. Gene content analysis indicated that the assembled genomes belonged to dsDNA, tailed phages in the order *Caudovirales*. Retrieval of an algal virus from a *Verrucomicrobia* cell indicated that unspecific attachment of virus particles to cells can be a problem when obtaining phage genomes from bacterial SAGs.

ssDNA Phages in the Marine Environment

Most of the viral metagenomic studies have focused on dsDNA phages. In comparison, less is known about the diversity of ssDNA and RNA phages in the marine environment, because their nucleic acid cannot be sequenced by the usual methods. To sequence ssDNA phages, their genome has to first be converted to dsDNA. This can be achieved using several methods, from which multiple displacement amplification (MDA) is the most used. However, MDA is not quantitative, because it is amplifying predominantly circular ssDNA phages, to the detriment of dsDNA phages. The method giving the most precise quantitative results from using an adaptase-linker amplification. Applying this method on marine samples, it was concluded that ssDNA phages represent not more than 5% of the marine phage community.

Fig. 9 Linking host identity and phage genomes using single-cell genomics.

Cultivated Phages Infecting Main Groups of Marine Bacteria

Phages of Marine Cyanobacteria – Cyanophages

Cyanophages are viruses infecting cyanobacteria. As oxygenic photoautotrophs, cyanobacteria are the main contributors to the oceanic primary production. Furthermore, many cyanobacteria are diazotrophs and thus they can assimilate N_2 gas and make it available for other organisms. This is especially important in ocean surface waters, where nitrogen is often a limiting nutrient for primary production. Cyanobacteria can be categorized into two major subgroups: unicellular and filamentous. The most abundant cyanobacteria in the oceans are the unicellular *Prochlorococcus* and *Synechococcus*. Due to their small size, they are also called picocyanobacteria. *Prochlorococcus* dominates in oligotrophic oceans between $40^\circ N$ and $40^\circ S$. The co-occurring genus *Synechococcus* is usually less abundant than *Prochlorococcus*, but it occurs also in sub polar regions, brackish and nutrient-rich environments.

Cyanophages have been studied quite intensively in the last decades. However, in comparison to their hosts, they are still poorly understood and the knowledge is severely biased towards certain host species and environments. The majority of the isolates and of the publicly available genomes belongs to phages of *Prochlorococcus* and *Synechococcus*, also called picocyanophages. Phages infecting filamentous and unicellular cyanobacteria form separate phylogenetic clusters.

Phages of unicellular cyanobacteria

More than 7000 picocyanophages have been isolated, from which at least 1000 have been sequenced in different studies. All isolated picocyanophages are tailed (see [Table 1](#)). The T4-like, S-TIM5 and S-CBWM1 picocyanophages have myoviral morphology. The T7-like picocyanophages have podoviral morphology. The other isolates have siphoviral morphology. Most of the picocyanophage in culture are either T4-like ([Fig. 10.1](#)) or T7-like.

Table 1 Cultivated cyanophages infecting unicellular cyanobacteria

Cyanophages	Genome type	Morphology	Life style	Host	Genome size (kb)	G + C content [%]	tRNAs #
T4-like	dsDNA	myoviral	strictly lytic	<i>Prochlorococcus</i> <i>Synechococcus</i>	170–250	~33–45	0–25
S-TIM5				<i>Synechococcus</i>	~161	~41	10
S-CBWM1				<i>Synechococcus</i>	~140	~52	34
T7-like		podoviral	strictly lytic, some potentially temperate	<i>Prochlorococcus</i> <i>Synechococcus</i>	41–48	~38–55	
P-SS2		siphoviral	strictly lytic, potentially temperate	<i>Prochlorococcus</i>	~108	~52	n.a.
S-CBS1					~30	~59	0
S-CBS2				<i>Synechococcus</i>	~72	~55	0
S-CBS3				<i>Synechococcus</i>	~33	~61	0
S-CBS4				<i>Synechococcus</i>	~69	~51	1
KBS2A			Strictly lytic	<i>Synechococcus</i>	~40	n.d.	0
A-HIS1				<i>Acaryochloris</i>	~55	~47	0
A-HIS2				<i>Acaryochloris</i>	~57	~47	0

Most cultivated phages infecting picocyanobacteria are strictly lytic. To date, no temperate picocyanophages have been isolated. However, induction experiments with environmental cyanobacteria suggest the existence of prophages. Furthermore, the *Prochlorococcus* phage P-SSP7 has an integrase gene, potentially being able to integrate into the host genome. Recently, a 100 kb putative prophage was predicted in the genome of *Synechococcus* WH8016. This prophage forms a new picocyanophage clade together with four MAVGs recruited from the Red Sea and Tara Ocean cellular metagenomes. This clade is found all over the oceans, in low abundance.

Several cyanophages, as for example S-CBWM1, S-TIM5 and those infecting *Acaryochloris* (see Table 1), have mitochondria-like DNA polymerase genes. Phylogenetic analysis indicates a likely common ancestor for the phage and mitochondrial DNA polymerase genes. It is likely, but not proven, that the DNA polymerase gene was transferred from a phage to an alpha-proteobacterial mitochondrial progenitor.

Picocyanophage and their host systems are the most studied amongst marine phage-host systems. Because several ecological principles derived from their study can be extended to other phage-host systems, they are further reviewed in this book article separately, in the “Marine Phage Ecology” section.

Phages of filamentous cyanobacteria

Filamentous cyanobacteria are free-living like the aggregate-forming *Trichodesmium* or associated with diatom hosts like the heterocyst-forming *Richelia* and *Calothrix*. They often form blooms in estuarine and marine environments. The production of cyanotoxins and oxygen depletion during and after the blooms can change the functioning of the whole ecosystem and can be harmful to the environment, human health and economy. Global warming is expected to enhance the frequency and intensity of cyanobacterial blooms. Cyanophages are thought to play an essential role in the termination of cyanobacterial blooms, but also in their maintenance due to community shifts between specific ecotypes. For example, phage lysis of *Nodularia* leads to the release of nitrogen and stimulates the growth of *Synechococcus*. A summary of the known phages infecting filamentous cyanobacteria is given in Table 2.

Phages of Marine Alphaproteobacteria

Phages of marine Pelagibacterales

Pelagibacterales, also known as SAR11, are small, vibrio-shaped chemoheterotrophic bacteria that constitute 20%–40% of all planktonic cells in the euphotic ocean and ~20% of cells in the deeper mesopelagic and bathypelagic waters. They are present in the oceans from pole to pole, but their largest numbers are found in stratified, oligotrophic gyres.

For a while, it was believed that the success of SAR11 clade is due to a lack of phage predators. However, this hypothesis was disproved by the isolation of several phages infecting *Pelagibacterales*, also called pelagiphages (Fig. 10.2). To date, there are only 15 known pelagiphage isolates, from which 14 are podoviruses and one is a myovirus related to T4 phages (see Table 3). Most pelagipodovirus isolates are placed within the proposed genus HTVC019Pvirus of the *Autographivirinae* subfamily and have the ability to propagate by both lytic and lysogenic cycles. They encode in their genomes a tyrosine integrase. Most likely this integrase catalyzes the integration of the pelagiphage in the host genome, through site-specific recombination in between the bacterial chromosomal attachment site (*attB*) and phage chromosomal attachment site (*attP*). The *attB* sites are various tRNAs present in the SAR11 genome, while the *attP* site is located in between the integrase and the RNA polymerase gene. Integration of HTVC019Pvirus phages has been shown both in SAR11 cultures and in metagenomic samples, suggesting that temperate pelagiphages could be implicated in ecological processes on broad scales.

PP				<i>Phormidium foveolarum</i>	~43	~46	0
Pf-WMP3					~43	~47	0
Pf-WMP4					~41	~52	0
NCTB ^a		myoviral	n.d.	<i>Trichodesmium</i>	~258	~42	0

^aUncultivated, genome obtained from a decaying bloom of *Trichodesmium* in the New Caledonian lagoon in the South Pacific Ocean.

Note: n.d. = not determined.

Table 3 Cultivated pelagiphages

Pelagiphages	Genome type	Morphology	Life style	Host genus	Genome size (kb)	G + C content	tRNAs #
HTVC019Pvirus	dsDNA	podoviral	lytic and lysogenic	<i>Pelagibacter</i>	37–42	~32–36	0–1
HTVC010P			strictly lytic		~35	~30	0
HTVC008M		myoviral	strictly lytic		~147	~34	0

Amongst cultivated pelagiphages, HTVC010P is the most abundant in the oceans. In the North and South Atlantic, it was found both in surface waters and in the DCM layer. HTVC008M was found only in a few stations in the Southern Atlantic, indicating latitudinal biogeography of the SAR11 phages. A study looking at the ratio between the phage and host transcripts in the coastal waters of the NE Atlantic, found a low ratio between cultivated pelagiphages and SAR11. This is suggestive of a low lytic activity of cultivated pelagiphages in coastal waters, not surprising considering that SAR11 generally has slow growth rates and that cultivated pelagiphages have long latent periods (16–22 h) and lower burst sizes (9–49 phages per infected cell).

SAR116 phages

SAR116 is an important group of heterotrophic bacteria in the surface ocean, with abundances as high as 10%. They have genes for proteorhodopsin-based photoheterotrophy, dimethylsulfoniopropionate, carbon monoxide and C1-metabolism, indicative of their involvement in marine biogeochemical cycles.

To date, only one phage infecting the marine SAR116 has been isolated, named HMO_2011. Its host is "*Candidatus* Punicispirillum marinum" strain IMCC13122. Phage HMO_2011 has a podoviral morphology and a ~55 kb dsDNA genome. As it is typical with phage genomes, most of the encoded genes are hypothetical. Amongst the annotated genes, the DNA polymerase and the putative methanesulfonate monooxygenase (MsmA) are noticeable. The DNA polymerase contains a partial DnaJ domain between the 3'-5' exonuclease and the DNA polymerase domains. Usually, this domain is found in molecular chaperones. The MsmA presence hints toward the involvement of the HMO_2011 phage in the C1 metabolism of SAR116.

The environmental distribution of the HMO_2011 phage was assessed using the Pacific Ocean Virome dataset. It was found that HMO_2011 is distributed mainly in the euphotic zones of both coastal and open ocean, and it is much less abundant in the aphotic zones. In the coastal waters of the NE Atlantic, HMO_2011 was highly active, as judged from the ratio between phage and host transcripts. This is in agreement with the shorter latency time (6 h) and bigger burst size (500 phages/infected cell) observed in culture.

Phages of marine Rhodobacteraceae – Roseophages

Marine *Rhodobacteraceae*, also known as the *Roseobacter* Group, are another important group of heterotrophic bacteria in the marine environment. They have a high metabolic versatility, being able to perform anoxygenic photosynthesis, metabolize a large variety of organic compounds, degrade dimethylsulfoniopropionate and produce various secondary metabolites. Most often, they are associated with micro- and macroalgae, with which they potentially engage in both mutualistic and pathogenic interactions.

Roseophages, that is phages infecting roseobacters, have been isolated for ten out of more than 70 described genera of marine *Rhodobacteraceae*. These ten genera are *Ruegeria*, *Sulfitobacter*, *Roseovarius*, *Dinoroseobacter*, *Roseobacter*, *Lentibacter*, *Celeribacter*, *Loktanella*, *Pelagibaca* and *Thiobacimonas*. Most of the roseophages are tailed, with dsDNA genomes and a podoviral or siphoviral morphology, and only two isolates have a ssDNA genome (see Table 4). There are two main groups of roseopodoviruses, the N4-like and the Cobavirus group, both strictly lytic. The roseosiphophages are more diverse, most of them being classified as

Table 4 Cultivated roseophages

<i>Roseophages</i>	<i>Genome Type</i>	<i>Morphology</i>	<i>Life style</i>	<i>Host genus</i>	<i>Genome size (kb)</i>	<i>G + C content</i>	<i>tRNAs #</i>
N4-like	dsDNA	podoviral	strictly lytic	<i>Ruegeria</i> , <i>Sulfitobacter</i> <i>Roseovarius</i> <i>Dinoroseobacter</i> <i>Roseobacter</i>	73–77	~43–51	0–15
Cobavirus group			strictly lytic	<i>Lentibacter</i> <i>Sulfitobacter</i> <i>Celeribacter</i>	39–41	~46–48	0
phiCB2047-A, phiCB2047-C			temperate	<i>Sulfitobacter</i>	~41	~59	0
Chi-like		siphoviral	strictly lytic, potentially temperate	<i>Ruegeria</i> <i>Loktanella</i>	57–61	~55–64	0
Cbk-like				<i>Ruegeria</i>	~147	~56	24–26
RDJLphi1				<i>Roseobacter</i>	~62	~58	
RDJLphi2				<i>Roseobacter</i>	~63	~57	0
vB_DshS-R5C				<i>Dinoroseobacter</i>	~78	~62	0
vB_ThpS-P1			temperate	<i>Thiobacimonas</i>	~39	~67	0
vB_PeaS-P1				<i>Pelagibaca</i>	~38	~64	0
vB_RpoMi-Mini, B_RpoMi-V15	ssDNA	icosahedral, non-tailed	strictly lytic	<i>Ruegeria</i>	4.2	~58	0

Cbk-like, Chi-like and Mu-like head group. The phages in the Mu-like group are temperate, the induction to lytic cycle being shown in deep-sea roseobacters. The other roseosiphophages are mainly strictly lytic, only some having certain genome characteristics, as for example integrase genes, which indicate a temperate potential.

Cobaviruses (Fig. 10.3) comprise several cultivated roseophages, as well as environmental phage genomes, forming a clade in the proposed *Siovirus* genus. Their genomes are split in two arms, with opposite transcriptional directions and separated by a rho-independent transcriptional terminator. The presence of direct terminal repeats (DTRs) at the end of the genomes indicate that cobaviruses replicate using a mechanism similar to the T7 phages. This involves the formation of long concatemeric DNA molecules as intermediates in replication and packaging, concatemers formed by the annealing of 3' single strands resulted at the DTR level during replication. Cobaviruses most likely lyse their host cells via the canonical holin-endolysin pathway. They are found worldwide in the euphotic ocean, mostly in coastal areas, but also in the open ocean. They are more numerous in bays or estuaries, as for example in the Goseong Bay, Delaware Estuary, Chesapeake Bay and Port of Los Angeles. Some cobaviruses were shown to be cosmopolitan, their genome being found for example both in the North Sea and in the Yellow Sea. In coastal environments, cobaviruses seem to be present throughout the year. Both cultivated and environmental cobaviruses encode in their genomes a cobalamin-dependent ribonucleotide reductase gene, related with similar genes from protist-associated microorganisms. This suggests that the habitat of cobaviruses are protist associated bacterial hosts, most probably vitamin B12 producers.

Recently, two ssDNA roseophages, distantly related to other *Microviridae* have been isolated (see Table 4). At 4.2 kb and 4 predicted ORFs, vB_RpoMi-Mini and B_RpoMi-V15 have the smallest genome size amongst known ssDNA phages. They encode a major capsid protein, a replication initiation protein, a peptidase, and a hypothetical protein. Similar proteins have been found in the genome of the *Novosphingobium tardagens* NBRC 16725, indicating the presence of a prophage or prophage remnant. The similarity of the peptidase gene with other genes from bacterial genomes, including genes located in prophage regions, indicate that ssDNA roseophages participate in horizontal gene transfer.

Phages of Marine Gammaproteobacteria

Vibriophages

Vibriophages are viruses infecting bacteria from the *Vibrionaceae* family. These bacteria represent a genetically and metabolically diverse group of heterotrophic bacteria, ubiquitous in the oceans. They can be free-living, however, they are more abundant in sediments or in associations with other marine organisms or organic particles. Furthermore, the group includes several pathogens, including *Vibrio anguillarum*, *V. parahaemolyticus*, *V. harvey*, and *V. vulnificus*. These pathogens infect more than 50 species of fish, mollusks and crustaceans. They can cause vibriosis, a malignant disease affecting the aquaculture industry globally, and food poisoning in people consuming infected, raw seafood. As a consequence, strictly lytic vibriophages are of special interest due to their potential use in phage therapy, as treatment for vibriosis.

The known marine vibriophages have a high diversity, with representatives in *Caudovirales*, *Autolykiviridae*, and *Inoviridae*. In the environment, vibriophages are found both in the water column and in association with animals. For example, a diverse and abundant vibriophage community has been found in oysters (*Crassostrea virginica*) from Delaware Bay, Ladysmith Harbor in British Columbia and from different estuaries in Gulf of Mexico. Vibriophages were present year-round in oyster tissue, with increased abundances in summer. This suggests that vibriophages are a common occurrence in oysters and most likely they play a

role in regulating *Vibrio* populations. Morphological characterization of vibriophages from oysters showed the presence of both tailed and non-tailed phages.

A few hundred lytic marine vibriophages have been isolated to date, from which 251 make part of the Nahant collection and have been genome sequenced. Most belong to *Caudovirales*, being either podo-, siphoviruses or myoviruses. About 20 isolates belong to the newly proposed *Autolykiviridae* family (see below). Caudoviruses in the Nahant collection have genome sizes ranging in between 21 kb and 348 kb. Notably, 32 phages carry putative CRISPR features. CRISPR/Cas systems are usually used by bacteria to protect themselves against phages. However, phages can encode their own CRISPR/Cas systems to evade host immunity. The first such system was shown in a vibriophage infecting *Vibrio cholera*. This suggests that the CRISPR features found in marine vibriophages could function in a similar way.

Autolykiviruses are non-tailed phages representing a novel family of the double jelly-roll capsid viruses. Their capsid has about 50 nm in diameter and it likely contains an inner lipid layer (see Fig. 10.7). Their linear, dsDNA genomes have 10-kb in length, terminate in inverted repeats and encode for ~20 proteins. Autolykiviruses have a broad host range, commonly killing hosts in multiple *Vibrio* species. This is in contrast to tailed phages, which usually infect few and closely related species. The isolated autolykiviruses are all strictly lytic. Autolykivirus-like prophages have been predicted bioinformatically in bacterial genomes and in contigs from marine metagenomes. Their *in vivo* activity has been recently demonstrated in two marine *Vibrio* species.

Prophages are abundant in marine vibrios and can encode (1) virulence factors, as for example Zonula occludens toxin (Zot); (2) bacterial host fitness factors, as for example RTX-toxins, collagenases, lipases, hemolysins, chondroitin AC lyases; and (3) genes involved in antibiotic and heavy metal resistance. In a recent analysis, 15% of the marine *Vibrio* isolates contained *Inoviridae* prophages encoding Zot. Inoviruses are filamentous ssDNA phages with a chronic life cycle. They integrate into the host genome and, upon induction, they release phage progeny without lysing the cell. Zot is known from *Vibrio cholerae* infected by the chronic CTX phage. Zot localizes in the bacterial membrane and increases intestinal permeability of the mammalian hosts. Zot containing prophages were found in isolates from coastal marine waters (e.g., *V. campbellii*), deep hydrothermal vents (e.g., *V. antiquarius* and *V. diabolicus*) and deep seafloor sediments (e.g., *V. diazotrophicus*). This suggests that harmless, environmental bacteria can acquire virulence traits from pathogenic donors and act as potential biological reservoirs of these genes in the environment.

Pseudoalteromonas phages

Pseudoalteromonas spp. are ubiquitous heterotrophic bacteria in the marine environment. Most often they are associated with particles, where they constitute up to 20%–60% of the microbial communities and they are involved in carbon export in the oceans. There are 12 cultivated phage groups infecting *Pseudoalteromonas*. Most of them are dsDNA phages, belonging either to *Caudovirales* (Fig. 10.4 and 10.5) or *Corticoviridae*, and one is a ssDNA phage (see Table 5).

Phage 327 is the first filamentous phage known to infect a *Pseudoalteromonas* strain from the Arctic Sea ice (Fig. 10.6). In culture, it decreases the host growth rate, cell density, and tolerance to H₂O₂ and NaCl, but it enhances its motility and chemotaxis. The latter might confer a survival advantage during the polar night, when nutrients are scarce.

Pseudoalteromonas virus PM2 is the first isolated and the most studied corticovirus. It infects via the lytic cycle the marine *Pseudoalteromonas espejiana* BAL-31. The capsid has ~56 nm in diameter and it contains an inner lipid bilayer. The genome is composed of a circular, highly supercoiled dsDNA molecule. It has only 10 kb in size and encodes for 21 proteins. Genome replication takes place via a rolling-circle mechanism. Through bioinformatics analysis, PM2-like prophages have been predicted in the genomes of cultivated marine *Proteobacteria*, as well as on contigs from marine metagenomes.

Phages of Marine *Bacteroidetes*

One important group of marine heterotrophs belongs to the *Bacteroidetes* phylum. Marine *Bacteroidetes* increase in abundance during algal blooms, being responsible for the degradation of biopolymers, for example polysaccharides, and thus are involved in recycling the organic matter derived from blooms. To date, most phage isolates for *Bacteroidetes* (see Table 6) infect the *Cellulophaga* genus, present in coastal environments and most often associated with macroalgae.

To date, 40 isolates grouped in 12 phage genera are known to lytically infect different strains of *Cellulophaga baltica*. Ten of the genera represent tailed dsDNA phages, with podo-, siphovirus and myovirus morphology. The phi38:1 podoviral isolate belongs to one of the most abundant viral clusters in the sunlit ocean, as discovered by viromics studies. The presence of a high number of tRNAs in its genome, correlated with a broader host range compared with isolates with fewer tRNAs, could explain in part the success of this phage and its relatives in the environment. Likely, the tRNAs allow the phage a better use of the host resources. Although phi38:1 phage has a broad host range, it does not infect all *C. baltica* strains with the same efficiency. In the original isolation host, phi38:1 infects 64% of the host cells, has a latent period of 70 min and a burst size of 8 phages per cell. In the alternative host, the infection efficiency of phi38:1 is lower. Only 20% of the host cells are infected, the latent period is ~5 h and the burst size is 40 phages per cell. Transcriptomics experiments showed that phi38:1 has similar expression patterns in the two hosts. On the other hand, the transcriptional response of the isolation and alternative hosts are significantly different. Upon phage infection, the alternative host overexpresses DNA degradation genes and underexpresses translation genes, resulting in a delayed phage replication and protein translation. These findings have implications for phage-infection ecology in nature. Because the microdiversity of both host and phages is expected to be high in the environment, it is likely that variable infection efficiencies are quite common.

Single-stranded DNA phages infecting *C. baltica* have been classified in two genera. The isolates from the Cba184likevirus genus are strictly lytic, have a genome size of ~6.5 kb, a capsid of ~30 nm and they are thought to represent a new subfamily of the *Microviridae*. The Cba482likevirus genus has strictly lytic phages with 11.5 kb genomes, the biggest length known for ssDNA phages. Furthermore, the capsid has a diameter of ~72 nm, twice bigger than other *Microviridae* representatives. Consequently, the Cba482likevirus is thought to represent a third lineage of ssDNA phages, besides *Microviridae* and *Inoviridae*. Sequence similarity indicates that *Zunongwangia profunda* (*Bacteroidetes*) harbors a Cba482likevirus prophage in its genome. This suggests that phages in the Cba482likevirus genus are capable of integrating into host genomes and becoming temperate.

Marine Phage Ecology

Phage Micro- and Macro-diversity in the Marine Environment

An ongoing discussion in virology regards the existence of the viral species. The biological species concept defines species as interbreeding individuals that remain isolated from other similar groups. Viruses don't reproduce sexually. However, they undergo homologous gene exchange, during simultaneous infection of the same host by multiple viruses. If the gene exchange

Fig. 11 Schematic representation of viral micro and macrodiversity.

would be confined within groups of similar viruses, then these groups would form discrete viral populations and could be defined as species.

One of the first indications that marine phages form discrete and stable genomic populations came from work on roseophages. Following the isolation of the SIO1 roseophage, a very similar phage was isolated 12 years later, indicating that phages are stable in time. Later on, several studies on cyanophages confirmed the existence of sequence discrete clusters. For example, in coastal waters of Southern New England, different clusters of cyanophages were stably maintained over a time span of 15 years. Furthermore, they exhibited a clear temporal and spatial pattern of abundance, suggesting that they occupy slightly different niches and that they represent viral ecotypes. From the different studies (e.g., [Brum et al., 2015](#); [Roux et al., 2016, 2018](#)), an empiric threshold for defining viral populations was established. This threshold was set at 95% nucleotide identity over at least 70% of the genome. Recently, the existence of discrete viral populations in the marine environment and their delineation by the above threshold was validated using the massive amount of data from the GOV2 dataset.

In an environmental sample, phages can be organized into different ecological levels (see [Fig. 11](#)). The lowest level is the individual phage. All individuals belonging to the same species form a population. The genetic diversity within the population, that is the number and proportion of different individual phages, is defined as microdiversity. The highest level of organization is the community, which is represented by all the phage populations in a particular sample. The number and the abundances of these populations are defined as macrodiversity. Usually, a viral community is formed from multiple viral populations, each with its own degree of microdiversity.

Diversity analysis showed that oceanic viral communities are grouped within meta-communities or ecological zones. In terms of diversity, this means that phage communities within one zone are more similar to each other than to phage communities from other zones. There are only five viral ecological zones within the world's oceans: (1) Arctic, (2) Antarctic, (3) bathypelagic (> 2000 m depth), (4) temperate and tropical epipelagic (0–150 m depth) and (5) mesopelagic (150–1000 m depth). These zones are similar to those observed for the marine bacterial communities, indicating that the main driver of phage diversity is the bacterial community composition. The highest macrodiversity was found in the epipelagic and Arctic zones, and the lowest in the Antarctic zone. The highest microdiversity was found in the mesopelagic and epipelagic zones, and the lowest in the Arctic. Furthermore, the epipelagic and the Arctic zones contained the higher number of zone-specific populations, which indicates high levels of endemism and suggest that these regions are virus biodiversity cradles.

Marine Phages as Factors Driving Bacterial Mortality and Diversity

Until the late 80's, when it was discovered that marine phages are highly abundant, it was believed that the main mortality factor for marine bacteria is grazing by protists. Now, it is recognized that viral lysis contributes significantly to bacterial mortality, shaping microbial community composition and diversity. It is estimated that 10 and 40% of bacterial cells are lysed by viruses.

Phage infections in the oceans are believed to follow a kill the winner model. In this model, phage infections are stimulated by increasing host cell densities and in turn, lead to the host population crash. In the same time, the coevolution of bacterial hosts and phages is a veritable arms race, in which the hosts find ways to evade the attack of phages and the phages evolve to counter the new defenses, to ensure that neither the predator nor the prey is driven to extinction.

This arms race results in a high microdiversity of both host and phage. This was shown in chemostat experiments in which a single bacterial strain and its phage were incubated for prolonged periods. Both heterotrophic hosts, e.g., *Cellulophaga baltica* MM#3, and photosynthetic hosts, e.g., *Synechococcus* sp. WH7803, were subjected to such experiments (Middelboe *et al.*, 2009; Marston *et al.*, 2012). In both cases, samples collected at different time points showed the evolution of several host and phage strains, with different degrees of resistance and virulence, respectively.

The mechanisms used by marine bacteria to escape phage predation are multiple, and still largely uncharacterized. In *Prochlorococcus*, resistance to phages is conferred by mutations impairing the attachment of phages to the cell surface. These mutations are localized especially in non-conserved, horizontally transferred genes from a single hypervariable genomic island, genes probably involved in the synthesis of phage receptors. Although these mutations protect *Prochlorococcus* from certain phages, they also decrease its growth rate and even allow more rapid infection by other phages. Phage-resistant strains continue to evolve, until they reach an improved growth rate and a narrower resistance range. This mechanism could explain why in nature many *Prochlorococcus* cells have high growth rates and are resistant to phages.

Bacterial lysis leads to the release of both dissolved organic matter (DOM) and of particulate organic matter (POM) into the environment. The released matter, especially the DOM, is re-utilized by heterotrophic microorganisms, instead of being transferred to upper trophic levels via grazing (see Fig. 12). This phenomenon is termed the “viral shunt”. Part of the released POM will likely aggregate because cell debris resulted from cell lysis are sticky, and will be exported to the deep ocean. Therefore, it has been hypothesized that phages participate in the biological pump through the stimulation of particle formation. Recently, it has been shown that *Synechococcus* and their phages are strongly associated with carbon export at 150 m in the subtropical, nutrient-depleted, oligotrophic ocean.

Diel Rhythms of Phage Infections in the Marine Environment

Most organisms have a circadian rhythm, in which physiological processes are regulated in a ~24 h cycle. These diel oscillations are observed both in pure cultures in the laboratory and in the marine environment as well. In unicellular cyanobacteria, the circadian clock directs oscillations in gene transcription levels, with the majority of transcripts peaking at dawn or dusk. For example, in *Prochlorococcus*, the photosystem I and II genes and the Calvin cycle genes are maximally transcribed at dawn, most likely in preparation for harvesting the light energy through the day. Because unicellular cyanobacteria are main primary producers in the oceans, most likely their diel rhythms influence the diel rhythms of the co-occurring heterotrophic bacteria and of their phages.

In laboratory settings, cyanophage infections are influenced by light at different steps in the infection cycle. Some cyanophages show light-dependent absorption onto their host cells, with a higher fraction of phages absorbing in the light than in the dark. Phage replication and burst size are positively correlated with light intensity, indicating that cyanophages use for their replication resources generated by the photosynthetic metabolism of their host cells.

In the marine environment, the influence of diel cycles on the host and phages was studied in the North Pacific Subtropical Gyre, a habitat representative of oligotrophic oceans. During an eight-day experiment, metagenomics and quantitative meta-transcriptomics were used to monitor the temporal abundances and transcriptional activities of most abundant dsDNA viruses. A small fraction of the assembled viral scaffolds showed a diel periodicity in their transcript abundance, with a peak in the afternoon to early evening. Most likely other viruses, with lower abundances, were subjected to diel rhythms, but the methods used were not sensitive enough to detect their transcripts. Amongst the diel transcripts, those for structural viral genes were highly abundant, indicating that virus production was following a diurnal lytic cycle. The majority of viral scaffolds showing a diel transcriptional activity were attributed to cyanophages, most likely infecting *Prochlorococcus*. The replication and cell division of *Prochlorococcus* also followed a diel periodicity, both processes peaking in the later afternoon to dusk. This indicates connectivity in between the diel cycle of *Prochlorococcus* and of their phages. Three possible scenarios can be envisioned to explain the peak in cyanophage transcripts in the afternoon. In the first, cyanophages infect their hosts through the 24-h cycle, but with different burst sizes. Because the host has more metabolic resources in the afternoon, those phages whose infection cycles overlap with the afternoon period have the highest burst sizes. In the second scenario, cyanophages released in the afternoon burst will infect their hosts during the night, but not advance in their infection cycle until the afternoon increase in host photosynthetic metabolism and DNA replication. In the third scenario, cyanophages absorption is enhanced by light, leading to a higher infection rate during the day and thus to an afternoon burst peak. Not only cyanophages exhibited diel variations in their transcript levels. Amongst the viral scaffolds with diel periodicity, one most likely represented a *Pelagibacter* phage. This indicates that not only phages of photosynthetic bacteria follow a diel cycle, but also those of heterotrophic bacteria.

Auxiliary Metabolic Genes in Marine Phages

With the increased availability of genome sequencing technologies, more and more phages have been genome sequenced. As expected, most of the genes found in phage genomes are essential for the production of new progeny, as for example those involved in nucleic acid replication, capsid, and tail assembly, cell lysis. However, much to our surprise, in the early 2000s it was discovered that cyanophages carry host genes involved in photosynthesis. Since then, more than 200 different genes were found which are not directly involved in phage replication, but rather are part of the host metabolic pathways. Those genes have been named auxiliary metabolic genes (AMGs). Not included in AMGs are genes involved in DNA packaging, nucleotide transport and metabolism, protein metabolism and assembly, DNA synthesis, replication, and repair. AMGs are classified in 2 classes: (1) class I includes AMGs present in the KEGG metabolic pathways and (2) class II includes proteins assigned only a general metabolic function or marginal metabolism (e.g., transport function) and thus, not present in KEGG.

The first photosynthetic AMGs discovered were *psbA* and *psbD*, encoding two major components of the photosystem II (PSII). They were found in the genome of S-PM2 myocyanophage, which infects *Synechococcus*. Since then, several other photosynthetic AMGs were detected. Environmental surveys show that they are common in marine picocyanophages and that they were likely acquired by horizontal gene transfer from infected hosts. Phage PSII genes are actively transcribed in *Prochlorococcus* infected with P-SSP7 podovirus. Likely, they are functional in photosynthesis and increase phage fitness. Recently, genes for both photosystem I and II were discovered in P-TIM68 myovirus infecting *Prochlorococcus*. These genes are expressed during phage infection and the encoded proteins are incorporated into host membranes. Not only is the host photosynthetic capacity maintained during phage infection, but the cycling electron flow in the photosystem I is enhanced. This suggests an increased production of ATP in infected cells, required probably by the phage replication machinery.

With the increase in the number of cultivated and environmental phage genomes, more and more AMGs have been found. Many of them are potentially involved in different biogeochemical cycles in the oceans. For example, *dsrC*, a gene belonging to the dissimilatory sulfur reductase operon, is usually found in sulfate/sulfite-reducing bacteria in anoxic environments and in sulfur-oxidizing bacteria in both oxic and anoxic environments. Recently, a *dsrC* gene was found on several viral contigs from the Global Ocean Virome. Another gene from the sulfur cycle, *soxYZ*, was found as well on phage contigs from the GOV dataset. All contigs with *dsrC* and *soxYZ* genes belonged to the T4-like viral cluster, one of the most abundant and ubiquitous clusters in the oceans. These findings suggest that marine phages manipulate sulfur cycling. Another example of AMGs is the *P-II* gene, which is involved in the regulation of the nitrogen metabolism in bacteria. It was found on several phage contigs in the GOV dataset, suggesting phage involvement in marine nitrogen cycling.

Transfer RNAs (tRNAs) in Phages and Their Role in Phage-Host Interactions

Transfer RNAs are present in the genomes of many phages, including cyanophages. These RNAs recognize specific codons in the mRNA and transfer the corresponding amino acid for incorporation into the growing protein chain. Due to the genetic code degeneracy, part of the 20 amino acids are encoded by multiple codons. In a particular bacterial host, depending on its genome G + C content, certain codons can be more frequent than others. As a result, the cellular tRNA pool can be biased toward the most

frequent codons. Generally, phages infect hosts with similar codon usage, because otherwise, the protein synthesis would be inefficient. To bypass differences in codon usage phages can encode tRNAs in their own genomes. Some cyanophages use this strategy to broaden their host range. For example, cyanomyophages with a higher number of tRNAs in their genomes are able to infect both low G + C content hosts (*Prochlorococcus*) and high G + C content hosts (*Synechococcus*). On the other hand, cyanomyophages with no tRNAs or a low number of tRNAs in their genomes are able to infect only *Prochlorococcus*. The number of tRNAs in the phage genomes is quite variable (see Table 1). The cultivated phage with the highest number of tRNA genes is the S-CBWM1 cyanophages. It has 34 tRNA genes in its genome. And potentially used these tRNAs to increase the translation efficiency for several unique phage genes, which have no homologs in sequences databases.

Conclusions

Phages are most likely present in all marine environments. They regulate the metabolism, structure, and composition of bacterial communities, thus impacting globally the marine biogeochemical cycles. Significant advancements in sequencing technologies have allowed characterization of marine phages on an unprecedented scale. Even so, much more remains to be known. For example, the host is unknown for most of the environmental phage contigs. As opposed to the sunlit ocean, the phage diversity of the deep-ocean and sediments is less known. Similarly, knowledge is sparse regarding marine ssDNA and RNA phages, as compared to dsDNA phages. Phage-host interactions have been studied only for a handful of phage-host systems. Also, little is known about lysogeny, how it shapes microbial communities and which factors are responsible for the lytic/lysogenic switch. To answer all these questions, a combination of cultivation-dependent and independent methods is necessary.

Nomenclature

CRISPR Clustered regularly interspaced short palindromic repeats

Cryo-EM Cryogenic electron microscopy

ds Double-stranded

MCP Major capsid protein

NaCl Sodium chloride

ss Single-stranded

T number Triangulation number

T4-like Virus morphology resembling bacterial myovirus T4

T7-like Virus morphology resembling bacterial podovirus T7

UV Ultra violet

VLP Virus-like particle

VPR Virus-to-prokaryote ratio

Glossary

Caudovirales Taxonomical order of viruses, which contains viruses with icosahedral heads, different types of tails, and linear dsDNA genomes.

Cryoconite hole Water-filled melt-hole on the surface of a glacier.

Cryogenic electron microscopy Electron microscopy technique where samples are rapidly frozen and then observed at cryogenic temperatures.

Cryopeg Water brine within permafrost.

Cryosphere The areas of the Earth where water is in solid state.

Deep-sea hydrothermal vent Geothermal vents at the seafloor of volcanically active areas.

Extremophile Organism that inhabits extreme environment, where one or more physico-chemical parameters reach their extreme values.

Halophile Organism that requires high salt concentrations for the optimal growth.

Hyperarid Extremely dry, with an aridity index below 0.05.

Metagenomics Metatranscriptomics, and metaproteomics, studies of pools of genomes, mRNA, and proteins, respectively, derived directly from environmental samples.

Myovirus Virus with an icosahedral head and a contractile tail.

Permafrost Ground that has remained frozen for at least two years' time period.

Phage Virus infecting bacteria.

Podovirus Virus with an icosahedral head and a short non-contractile tail.

Polyextreme environment Environment with two or more physico-chemical parameters reaching their extreme values.

Prophage Phage genome integrated into the host cell DNA or existing as a plasmid in the host cell cytoplasm.

Siphovirus Virus with an icosahedral head and a long non-contractile tail.

Triangulation number Square of the distance between two adjacent five-fold vertices of an icosahedral viral capsid.

Virome Specific pool of nucleic acids that constitute a viral community within an ecosystem.

Virophage Small dsDNA virus whose replication is dependent on the co-infecting giant virus.

Virus-like particle In microscopy: particle that morphologically resembles a virus.

Vitrification Rapid cooling process that suppresses the formation of ice crystals.

Introduction

The availability of liquid water within a cell can be considered as one of the prerequisites for life, enabling a proper functioning of essential cellular processes, such as enzymatic reactions and nucleic acid metabolism. These requirements are easily met in an environment with 20–30°C temperature, 1 atm pressure, and available water. However, in the Earth's extreme environments, physico-chemical parameters like temperature, pressure, salinity, ultra violet (UV) radiation and pH reach extreme values. The word *extreme* is derived from the Latin *extrēmus*, which means uttermost, utmost or last. Indeed, the conditions for life in extreme environments can probably best be described as “at the limit”. Majority of organisms cannot tolerate such conditions, indicating that different types of extreme environments may have low species diversity and some large taxonomic groups of organisms can be totally absent.

Nonetheless, several extreme environments on the Earth, such as polar sea ice, hypersaline environments, volcanic springs, and deep-sea hydrothermal vents, are actually flourishing with life. These environments are inhabited by extremophiles, organisms that

not only tolerate, but also require the surrounding extreme conditions for survival. Most extremophiles are microorganisms. Archaea often dominate in various extreme environments, but bacteria and eukaryotes can also be abundant.

Viruses of extremophiles exceed the number of their archaeal, bacterial or eukaryotic host cells by ten- to hundred-fold and are often the only predators in various ecosystems of extreme environments. Due to the low species diversity of their host organisms, viruses of extremophiles are important evolutionary players in shaping the dynamics and structure of microbial communities. Even today, extreme environments remain largely unexplored territories and the overall number of extremophilic phage isolates is low compared to the non-extremophilic ones. Genome sequences of the described phages of extremophiles, as well as metagenomes obtained from extreme environments typically contain low number of hits to common databases. Detailed molecular studies of virus-host interactions in extreme environments are scarce and much more research is needed in order to better understand these unique phage-host systems. Moreover, some extreme environments, such as volcanic hot springs, are suggested to resemble the conditions on the early Earth and could thus provide valuable information about the origin and evolution of life. In addition, studies on extremophiles and their viruses are also important regarding astrobiology, i.e., how microorganisms could survive in extra-terrestrial conditions. The research on viruses and their extremophilic hosts can also add insights into the biodiversity on our planet, providing knowledge needed for predicting the effects of climate change.

This article concentrates on extremophilic bacterial viruses, *phages*, but archaeal viruses are also mentioned when relevant. The available data on extremophilic phages reviewed here have been obtained by different methods, each of which has its own limitations. For example, by electron microscopy, virus-like particles (VLPs), cellular membrane vesicles or staining artefacts may be visualized together with bona fide viruses. For simplicity, the different environments reviewed here have been categorized into e.g., thermal, cold, or hypersaline. In fact, several of the introduced environments are polyextreme, meaning that they are subjected to two or more extreme parameters. As with all the other studied environments, phages with icosahedral heads, different types of tails and linear double-stranded (ds) DNA genomes dominate in most extreme environments, while still very little is known about extremophilic enveloped viruses or viruses with RNA genomes. We expect that future research on extremophilic phages will reveal many novel structures and functions helping to understand the life around us.

Phages in Hypersaline Environments

Hypersaline environments are characterized by high salt concentrations. In such environments, the dominant salt is usually NaCl and the overall proportion of ions corresponds to that in seawater, but some hypersaline waters, e.g., the Dead Sea, may have ions in other proportions. The examples of hypersaline environments are solar salterns, brine springs, hypersaline lakes and ponds, deep-sea brine pools, halite deposits, salt mines, saline soils, and salty food products. *Halophilic*, i.e., “salt-loving”, organisms flourish in hypersaline environments. Although some marine organisms may be slightly halophilic, here, by *halophiles* we refer to organisms that are found in a salinity higher than that of seawater. *Halophiles* may be slight, moderate, or extreme, requiring 1%–3% (0.2–0.5 M), 3%–15% (0.5–2.5 M), or 15%–30% (2.5–5.2 M) NaCl, respectively, for optimal growth. Halophiles are known within all three domains of life, but archaea and bacteria are especially abundant in hypersaline environments.

High numbers of VLPs (up to 10^9 VLPs ml^{-1}) of various morphologies, including spindle-shaped, spherical, tailed, filamentous, as well as some exceptional shapes, such as stars and hooks, have been reported for hypersaline environments. For example, high VLP densities (10^8 – 10^9 VLPs ml^{-1}) and high abundance of tailed icosahedral VLPs, typical for the phages belonging to the order *Caudovirales*, have been found in the alkaline (pH ~10), hypersaline Mono Lake, USA (Fig. 1). In those samples, siphoviruses and myovirus-like particles were the most abundant among tailed VLPs, but podoviruses were also present. However, the VLPs observed in hypersaline environments, especially those of unusual forms, may represent mostly archaeal viruses, given that archaea usually dominate at high salt concentrations. Most of the phages described so far display tailed icosahedral particles, but in hypersaline environments, even tailed icosahedral particles may also refer to archaeal tailed viruses.

Metagenomic, metatranscriptomic, and metaproteomic studies have revealed that viral communities are dynamic, specific, and diverse in hypersaline environments. Metagenomics of the sediment samples from the Great Salt Lake (15% total salinity, pH 7.4), USA, revealed that bacteria dominated in the prokaryotic community, with *Proteobacteria*, *Firmicutes*, *Bacteroidetes*, *Actinobacteria*, *Chloroflexi*, *Cyanobacteria*, and *Planctomycetes* as the most dominant phyla. In the viral fraction of the metagenome, sequences related to the members of the order *Caudovirales* dominated, with lambda-like, T4-like, and *Cellulophaga*-associated phages being particularly abundant. The sequences of tailed phages have been also found in other hypersaline environments, e.g., deep-sea anoxic brines of Red Sea or cold hypersaline Deep Lake in the Antarctica. The presence of prophage sequences, viral functional genes, and virus defense systems, such as clustered regularly interspaced short palindromic repeats (CRISPRs), in bacterial genomes retrieved from high salinity environments suggests active viral-mediated gene transfer and dynamic virus-host interactions.

At least 31 halophilic phages have been isolated to date (Table 1). These phages infect hosts of various genera and have been isolated from distant hypersaline environments all over the world or induced from halophilic bacterial strains. The first eight viruses infecting *Salinibacter ruber*, an extremely halophilic bacterium commonly found in hypersaline environments, have been isolated only recently, while previous studies of metavirome and metatranscriptome from Santa Pola solar saltern, Spain, have already suggested the presence of active phages infecting *S. ruber*. A few phages have been isolated from soda lakes, which are characterized by high sodium carbonate concentrations and high pH values. Both virulent and temperate halophilic phage isolates are known, although for many of them, life cycles have not been studied in sufficient detail. Most of the isolated halophages

Fig. 1 Transmission electron micrographs of viruses from depths of 2 m (A–C), 16.5 m (D–F), and 35 m (G–I) in Mono Lake. Reproduced from Brum, J.R., Steward, G.F., 2010. Morphological characterization of viruses in the stratified water column of alkaline, hypersaline Mono Lake. *Microbial Ecology* 60 (3), 636–643. doi:10.1007/s00248-010-9688-4.

display tailed icosahedral particles, typical for phages classified into the order *Caudovirales*. As for other morphotypes, one tailless icosahedral virus, SSIP-1, which infects *Salisaeta* sp., was isolated from Sedom Ponds, Israel, and one spherical virus, JMT-1, which infects *Chromohalobacter*, was isolated from Yuncheng Saline Lake, China. For many isolates, there are no available data on their genome organization, others have dsDNA genomes in either linear or circular conformation and of variable length (Table 1).

High-resolution image reconstructions based on cryogenic electron microscopy (cryo-EM) revealed that the icosahedral capsid of CW02, podovirus infecting *Salinivibrio*, is decorated with turret-like structures at icosahedral vertices and its major capsid protein (MCP) has a conserved HK97-fold. A so-called canonical HK97-fold, which was originally observed in phage HK97, is found in tailed phages, eukaryotic herpesviruses and in HSTV-1, an archaeal tailed virus. The conservation of certain protein folds and overall virion architectural principles observed across various viral groups has led to the idea that all viruses may be in principle classified into a limited number of structure-based lineages, including the HK97-like lineage. The other halophilic tailless icosahedral bacteriophage, SSIP-1, (Fig. 2) displays structural features typical for viruses grouped into the PRD1-adenovirus-like structural lineage. This lineage comprises tailless icosahedral inner-membrane containing (except membraneless adenovirus) dsDNA viruses, including both prokaryotic and eukaryotic ones, as well as virophages. Viruses belonging to the PRD1-adenovirus-like structural lineage are either extremophilic or

moderate, e.g., phages PRD1, PM2, P23-77 (see below), archaeal viruses STIV, SH1, HHIV-2, HCIV-1, algal virus PBCV-1, human adenovirus, and the virophage Sputnik.

Phages in Thermal Environments

Thermophilic, i.e., “heat-loving”, organisms inhabit hot environments, where temperature ranges from ~40 to ~80°C, while *hyperthermophiles* grow optimally at temperatures above 80°C. Such hot environments include terrestrial volcanic sites, non-polar deserts, hydrothermal springs, submarine hydrothermal systems, and oceanic basement subsurface. In addition, thermophilic microorganisms can be found from various artificially made environments, such as dairy production plants, water heaters, and compost piles.

Hyperthermophilic archaea tend to dominate in the hottest environments (at above 70°C), while thermophilic bacteria are often dominant at milder temperatures (~40–70°C). Viruses are abundant and active players in microbial communities inhabiting thermal terrestrial and marine sites. Moreover, in thermal environments where temperature exceeds the upper limit for eukaryotic life (~60°C), prokaryotic viruses are the only predators, controlling host abundance and affecting organic and inorganic nutrient cycling.

Terrestrial Hot Springs

Terrestrial thermal springs are sites where geothermally heated groundwater is released at the land surface. These sites are characterized by temperatures of ~35°C up to the boiling point, a pH range of 1–9, and various ion composition. Thermal springs are found all over the planet, but some regions, such as Yellowstone National Park in the USA, are particularly rich in hot springs and geysers.

Quite different VLP densities have been reported for hot springs, ranging roughly from 10^4 to 10^7 VLPs ml^{-1} . Virus-to-prokaryote ratios (VPRs) detected in hot springs are typically lower when compared to moderate environments. Electron microscopic examinations of VLPs in Yellowstone hot springs revealed a variety of different morphotypes, including rod-shaped, lemon-shaped, and filamentous particles typical for hyperthermophilic archaea, novel morphotypes (zipper-like, pleomorphic, and other complex particles), and tailed particles. The latter ones were observed only in neutral or mildly alkaline springs and may represent bacteriophages or archaeal viruses. A complete genome sequence of the OS3173 phage, which presumably infects *Aquificales*, was retrieved from a metavirome from the alkaline Octopus hot spring (pH ~ 8.5), Yellowstone. Metagenomic studies of acidic springs in Iceland, Italy, and Yellowstone National park (76–90°C, pH 1.8–5.5) showed the overall predominance of archaeal viruses over bacteriophages. However, the fraction of phages might have been underestimated due to a bias of reference databases, which contain significantly more hyperthermophilic archaeal viral sequences compared to those of thermophilic bacteriophages. Sequences related to the members of the order *Caudovirales* were abundant in samples obtained from a hot spring in Grensdalur, Iceland (85°C, pH 5), and a partial genome of a presumably *Hydrogenobaculum* phage, HP1, was reconstructed from the same sample.

Cyanophages have been reported to dominate in some hot springs. Microscopy analysis of Brandvlei hot spring (60°C, pH 5.7), South Africa, showed the presence of both archaea-specific VLPs and tailed particles. Lambda-like siphoviruses dominated, while podoviruses, as well as regular-sized and jumbo myoviruses, were also present. Metaviromic analysis demonstrated the prevalence of *Caudovirales*-related sequences and revealed a large fraction of genes typical for cyanophages. Partial genomes of two phages, cyanophage BHS3 and putatively *Gemmata* phage BHS4, were also obtained from Brandvlei hot spring metavirome. The predominance of tailed VLPs was also shown in cyanobacteria-dominated phototrophic mats in Porcelana hot spring (46–70°C, pH ~ 7), Chile (Fig. 3). Metagenomic analysis of the same samples confirmed the dominance of phages belonging to the order *Caudovirales* and allowed a full genome reconstruction of a T7-like thermophilic cyanophage (podovirus), TC-CHP58, which presumably infects *Mastigocladus* sp. However, no thermophilic cyanophages have yet been isolated.

The most numerous thermophages isolates have been obtained on *Thermus* strains (Table 2). In a large sampling of alkaline hot springs in Iceland, New Zealand, Russia (Kamchatka), and the USA, arranged by the Promega corporation, 115 phages were isolated on seven *Thermus* strains. About 45% of the obtained isolates were tailed phages (myo- and siphoviruses). In addition, tailless icosahedral and filamentous phages were present. In this sampling, two *Thermus thermophilus* siphoviruses, P23-45 and P74-26, with exceptionally long tails (~ 800 nm) were isolated from Kamchatka hot springs, Russia. Later, TSP4, a similar *Thermus* siphovirus with a 785-nm long tail, was isolated from Tengchong hot spring, China, suggesting a worldwide distribution of this unusual siphovirus type. In addition, another *Thermus thermophilus* siphovirus, G20c, isolated from Kamchatka hot springs shows high sequence similarity to P23-45 and P74-26.

Thermus phages P23-77 and IN93 display similarities to tailless icosahedral inner-membrane containing dsDNA viruses SH1, PH1, HHIV-2, HCIV-1, and SNJ1, which infect halophilic archaea. Consequently, these phages and archaeal viruses have been classified into one viral family, *Sphaerolipoviridae*. In addition, two other *Thermus* phages, P23-72 and P23-65 H, have been proposed to belong to the same family. Cryo-EM-based image reconstructions (Fig. 4) revealed that P23-77 virion consists of an icosahedral protein shell and an internal lipid membrane, which encloses the dsDNA genome. At the five-fold symmetry positions, P23-77 virion is decorated with spike complexes, which most probably serve for host recognition. The capsid lattice arrangement (pseudo-hexameric with $T = 28$ symmetry) seems to be conserved within the family *Sphaerolipoviridae*, while spike complexes display various forms. Overall virion structural organization, as well as MCP folding, places P23-77, together with other sphaerolipoviruses, within the PRD1-adenovirus structural lineage.

Deep-Sea Hydrothermal Vents

Seafloor had been considered as a desert-like environment, where life can be barely found, until the discovery of hydrothermal vent systems in the late 1970s. Since then, most studies on life in the deep ocean have concentrated around underwater thermal systems as the hotspots of life, surrounded by dark, cold and nutrient deficient ocean waters. Deep-sea hydrothermal vents are unique extreme environments with huge gradients of temperature, pH, and dissolved chemical compounds, not to mention high hydrostatic pressure. Vent fluids may reach as high temperatures as 400°C at the top of the chimney, but the temperature of fluids drops sharply, when they are mixed with the surrounding cold seawater (0–4°C). Due to the mixing of extremely hot and cold

Fig. 2 Icosahedral reconstruction of the SSIP-1 virion. (A) Electron micrograph of SSIP-1 virions vitrified at 9% (wt/vol) salt water (SW) buffer (see composition in Table S2 in original publication). Three spikes are indicated with black arrowheads (Scale bar, 50 nm.) (B) Central slice through an icosahedral reconstruction. *Inset* shows a radially averaged density profile. DNA (D), membrane (M), capsid (C), and spikes (S) are indicated. Twofold, threefold, and fivefold axes of icosahedral symmetry are indicated by an ellipse, a triangle, and a pentagon, respectively. Three concentric layers of DNA are indicated with asterisks. Lipid bilayer is interrupted by transmembrane densities at the threefold axes of symmetry (triangle). (C) Radially colored isosurface representation of the reconstruction with an arbitrary handedness is rendered at 2σ above the mean density. Color bar shows radial coloring. *Inset* shows a model lattice exemplifying the $T = 49$ icosahedral triangulation. Geometrical arrangement of the capsomers is given by the relationship $T = h^2 + hk + k^2$, where h and k define the lattice point. Here $h = 7$, $k = 0$. The two frontmost fivefold vertices are in red. (D–F) Six times magnified close-ups of the reconstruction taken along the (D) twofold, (E) threefold, and (F) fivefold axes of symmetry. Reproduced from Aalto, A.P., Bitto, D., Ravantti, J.J., *et al.*, 2012. Snapshot of virus evolution in hypersaline environments from the characterization of a membrane-containing *Salisaeta* icosahedral phage 1. *Proceedings of the National Academy of Sciences of the United States of America* 109 (18), 7079–7084. doi:10.1073/pnas.1120174109.

Reproduced from Guajardo-Leiva, S., Pedrós-Alió, C., Salgado, O., Pinto, F., Díez, B., 2018. Active crossfire between cyanobacteria and cyanophages in phototrophic mat communities within hot springs. *Frontiers in Microbiology* 9, 2039. doi:10.3389/fmicb.2018.02039.

waters, a steep gradient of pH and fluid chemistry is formed within meters from the fluid emission site. As a result, a variety of microenvironments is formed within hydrothermal vents systems, hosting very diverse forms of life. Chemosynthesizing archaea and bacteria serve as primary producers in these communities.

Viruses are ubiquitous in both deep and shallow underwater vents, except that no VLPs have been found on the interior parts of chimney structures. Virus particles are typically more abundant in vent systems than in the surrounding seawater: 10^4 – 10^5 VLPs ml^{-1} observed in deep-sea waters and 10^5 – 10^7 VLPs ml^{-1} in hydrothermal vent systems. In deep-sea hydrothermal environments, VPR is typically not higher than that in seawater (≤ 10). Sequence and microscopy analyzes have revealed the presence of tailed bacteriophages in various hydrothermal vents and even hundreds of meters below the seabed surface. VLPs of various shapes were observed in the brackish-marine sediments of the Baltic Sea (Fig. 5), including tailless and tailed icosahedral particles and VLPs inside cells. The analysis of g23 gene, which encodes MCP of T4-like myoviruses, revealed diverse groups of T4-like phages, including cyanophages, in the Baltic Sea subsurface sediments.

Sampling of hydrothermal vents is highly difficult not only due to technical and logistical constraints, but also due to the very dynamic nature of these systems. Cells and viruses found in plume fluid samples may in fact originate from the surrounding seawater, surface chimney sediments, or subsurface seabed, as water masses are constantly in movement. Perhaps, this partially explains the fact that the available literature contains controversial reports regarding the specificity of viral community composition, when the vent and background seawater metagenomes are compared. Metagenomes obtained from hydrothermal vents display high enrichment with proviral sequences and mobile genetic elements in cells and auxiliary metabolic genes in viruses, suggesting that lysogeny is a common virus life strategy in these environments. Genomes of phages presumably infecting sulfur-oxidizing bacteria, which are ubiquitous marine chemolithoautotrophs, were retrieved from metagenomic datasets sampled from hydrothermal vent plumes in the Pacific Ocean. These dsDNA viral genomes contained auxiliary metabolic genes involved in elemental sulfur oxidation, suggesting a role in supplementing the metabolism of sulfur-oxidizing bacteria and thus affecting sulfur cycling in deep sea.

To the best of our knowledge, only eight phages infecting bacteria from deep-sea hydrothermal vents have been obtained to date (Table 2). All of them have been either induced or spontaneously isolated from the host cultures, i.e., no phages have been yet isolated directly from deep-sea hydrothermal vent samples. The known isolates are all tailed phages obtained from the strains belonging to *Bacillus*, *Geobacillus*, *Nitratiruptor*, and *Marinitoga* genera isolated from Pacific or Atlantic deep-sea hydrothermal systems. Interestingly, the virions of MPV1, a siphovirus infecting *Marinitoga piezophila*, carry a host plasmid in addition to the viral DNA, highlighting the horizontal gene transfer in the deep-sea thermal systems.

Hot Deserts

Hot hyperarid deserts represent complex environments, where organisms have to adapt to multiple extreme conditions, including broad temperature variations, water limitation, intensive UV radiation and nutrient starvation. In spite of multiple extremities, microbial cells and viruses inhabit the soils of hot deserts, although viral abundances are low. Tailed virus particles were observed in the samples of soils from the Namib, Mojave, and Sahara deserts. Hot desert metaviromes have also shown to

^aNd, not determined.^bBased on genome sequence analyzes.

contain phage sequences, e.g., phages associated with bacteria belonging to the following genera: *Bacillus*, *Rhizobium*, *Geobacillus*, *Actinoplanes*, *Mycobacterium*, *Streptomyces*, and *Myxococcus*. The treatment of desert soil samples with mitomycin C has significantly enhanced the recovery of viral particles from the samples, suggesting that lysogeny may be a prevalent lifestyle of viruses in hot desert soils.

Phages in Polar and Other Cold Environments

About 10% of the Earth land surface is permanently covered by ice and snow, extending up to roughly 30% during winter in the Northern hemisphere. Furthermore, ocean deep waters, which account for 90% of the total ocean volume, are cold (0–3°C), and up to ~5% of the area of the global ocean is covered by sea ice. Thus, the biosphere provides a great variety of cold biotopes,

Fig. 4 (A) Organization of P23-77. Cryo-electron micrograph taken at 2.7 μm underfocus showing P23-77 viral particles (white arrow), with a diameter of 78 nm. Thin spikes, which might be used in the infection of the host, are visible on some particles (black arrow). The viral membrane inside the protein capsid is visible in empty particles (inset, underfocus 2.2 μm). Bar, 100 nm. (B) A 0.28 nm thick central section through the virion. Symmetry axes are indicated with a black ellipse (2-fold), triangle (3-fold) and pentagon (5-fold). Proteins connecting the viral capsid and the underlying lipid bilayer at the five-fold vertexes are visible. D (DNA), M (membrane) and C (capsid shell). Bar, 20 nm. Protein is black in A and B. (C) Radial density profiles of the icosahedral reconstruction of the intact virion (solid line) and the empty particle (dotted line). For calculation of the radial profiles both the full and the empty particle reconstructions were calculated to 3.0 nm resolution. Reproduced from Jaatinen, S.T., Happonen, L.J., Laurinmäki, P., Butcher, S.J., Bamford, D.H., 2008. Biochemical and structural characterisation of membrane-containing icosahedral dsDNA bacteriophages infecting thermophilic *Thermus thermophilus*. *Virology* 379 (1), 10–19. doi:[10.1016/j.virol.2008.06.023](https://doi.org/10.1016/j.virol.2008.06.023).

where *psychrophilic* or *psychrotrophic* organisms thrive. *Psychrophiles*, i.e., “cold-loving” organisms, grow and reproduce optimally at the temperatures ranging roughly from 0 to 15°C (max. ~20°C) and often are also capable to survive at sub-zero temperatures. Psychrotrophic organisms are cold-tolerant, they may survive at the above mentioned temperatures, but require temperatures

above 15°C for the optimal growth (max. ~30°C). In many habitats, psychrophiles have to tolerate also other extreme factors, such as high pressure in cold deep-sea waters or high salinity in some Arctic and Antarctic lakes.

Diverse and active microbial communities inhabit the cryosphere. Because of the absence or low abundance of grazers, these communities are characterized by high prokaryotic mortality due to viral infections. In low temperature ecosystems, viruses have a particularly important role in driving microbial evolution and, indirectly, the cycling of carbon. Although the viral component of cryosphere remains largely unstudied, it is already evident that viruses are abundant in various cold environments, such as polar freshwater and saline lakes, glaciers, sea ice, polar soils, snow, and permafrost.

Polar Oceans

Metagenomic analysis of viromes from four different oceanic regions, including the Arctic Ocean, has revealed that global and regional marine viral diversity is high, varying in different latitudes, and there are both highly widespread and endemic marine viruses in the global ocean. The analyzes of surface water dsDNA viromes sampled in the Antarctic Prydz Bay revealed high abundance of tailed phages, including *Flavobacterium* phage 11b (Table 3). A substantial number of prophage sequences and viral genes, especially phage terminase genes, has been detected within bacterial genomes from both Arctic and Antarctic Ocean waters, indicating active horizontal gene transfer in these cold polar waters.

Glaciers

Glaciers, especially supraglacial (top) biotopes, host a variety of microorganisms, including bacteria and their viruses. Due to the absorption of sun heat by cryoconite, i.e., dark rock particles and organic sediments on the surface of glaciers, the underlying ice melts, forming cryoconite holes filled with water (Fig. 6). These holes are the hotspots of microbial life in glaciers. Positive correlation between bacterial and viral abundances, high numbers of virus-like particles (10^6 – 10^7 VLPs ml⁻¹), high virus infection and production rates, but low virus burst size have been reported for cryoconite holes. Molecular studies targeting T4 MCP gene, g23, on glacier surfaces in Svalbard, Arctic, revealed a diverse community of T4-like phages, including both novel and cosmopolitan phages. The analyzes of metaviromes from cryoconite hole ecosystems of Svalbard glaciers and the Greenland Ice Sheet showed high diversity of bacteriophages, suggesting novel virus groups and unusual virus life strategies. At least eight

Fig. 6 Cryoconite holes. (a) Schematic diagram of cryoconite hole formation. Cryoconite holes at the surface of glaciers are formed because organic and inorganic particles, which are darker than the surrounding white icy surface, absorb the solar radiation better than the ice. The heated debris therefore melts into the ice forming holes, which provide nutrients and liquid water for microbial activity. (b) Example of open cryoconite holes in the Arctic. (c) Example of entombed cryoconite hole in Antarctica. Photo courtesy Liz Bagshaw. Reproduced from Anesio, A.M., Bellas, C.M., 2011. Are low temperature habitats hot spots of microbial evolution driven by viruses? *Trends in Microbiology* 19 (2), 52–57. doi:10.1016/j.tim.2010.11.002.

cold-active tailed bacteriophages have been isolated from glacial melt water (Table 3): *Flavobacterium* phages MYSP03, MYSP08, and MYTP08, *Janthinobacterium* phage MYSP06, *Bacillus cereus* phage VMY22, and *Pseudomonas* phages MYBP2A-15, MuztagBP1, and MuztagBP2.

Polar Lakes

Culture-independent studies have revealed high virus loads in Antarctic freshwater and saline lakes. VLP concentrations appear to be high in polar saline lakes compared to temperate marine waters, but lower in polar freshwater bodies than in temperate freshwater systems. Microscopic examinations of Antarctic freshwater and saline lakes demonstrated various virus morphologies, including tailed and tailless icosahedral particles. Metagenomic data have also showed high relative abundance of the phages belonging to the order *Caudovirales*. Based on the available viromes, Arctic and Antarctic freshwater viral communities are similar at general taxonomic level, but diverse and specific at a fine level. A large portion of sequences from polar metagenomes has no similarities to the data stored in common repositories, highlighting a need for more comprehensive sampling of cold environments.

Sea Ice

In sea ice, microbial communities thrive in brine channels and pockets, which are formed within the ice in the process of seawater freezing. Algae, bacteria, and their viruses dominate in these unique microenvironments. It has been shown that bacterial growth and viral production in sea ice brines is possible even at -12°C . Bacteriophage densities range roughly from 10^5 to 10^8 VLPs ml^{-1} in sea ice. Higher concentrations of bacteria and viruses have been reported for sea ice compared to seawater, pointing to active virus production within the ice and/or active enrichment with viruses from seawater. The analysis of genome sequences of sea ice bacteria indicated that gene transfer mediated by viruses is abundant in sea ice. To date, the majority of sea ice virus-host systems have been isolated from the Arctic (Fig. 7), but recently, the first four virus-host systems have been obtained also from the Antarctic sea ice (Table 3).

Permafrost

Viruses have been observed in Siberian, Antarctic, and Arctic permafrost. The hotspots of life in frozen soils are cryopegs, highly saline pockets or brines within permafrost layers. The study of cryopegs in permafrost near Barrow, Alaska, showed greater VLP concentrations in cryopegs (up to 10^7 VLPs ml^{-1}) than in the associated ice wedge (up to 10^5 VLPs ml^{-1}). Microscopic images of Barrow cryopeg filtered brine revealed VLPs resembling siphoviruses and virome analysis showed that phages belonging to the order *Caudovirales* dominated in the taxonomic composition among sequences having hits to known viruses. Unclassified

Fig. 7 Transmission electron micrographs of the negative stained samples of '1 × purified' ice phages. a Phage 1/4, b phage 1/32, c phage 1/41, d phage 1/40 isolated from Baltic sea ice. Scale bars 100 nm. Note that only sections A–D from original figure are used here. Reproduced from Luhtanen, A.-M., Eronen-Rasimus, E., Kaartokallio, H., 2014. Isolation and characterization of phage–host systems from the Baltic Sea ice. *Extremophiles* 18 (1), 121–130. doi:10.1007/s00792-013-0604-y.

members of the order *Caudovirales* were also prevalent in the taxonomically identifiable part of the metavirome obtained from peatland soils along a permafrost thaw gradient in Stordalen, Sweden.

Other Cold Environments

Metagenomic studies have revealed the presence of bacteriophages in polar soils and snow. Public snow metagenomes contain a portion of viral sequences, albeit small, and prophages have been induced from *Paenibacillus* isolates obtained from top snow in the Antarctic. Studies of cold hyperarid desert soils in Antarctica showed high VLP densities ($\sim 10^8$ VLPs g^{-1} of dry soil), which is substantially higher than in hot hyperarid desert soils, and very high VPRs (up to 8200). Sequence analysis demonstrated that the members of *Caudovirales* were dominant among identified viruses, with *Mycobacterium* phages being particularly abundant. Interestingly, temperate bacteriophages (siphoviruses SpaA1 and BceA1) with an unusual arrangement of genes were retrieved from the Antarctic soils.

About 20 cold-active lytic tailed bacteriophages have been isolated from the Napahai wetland located in the middle of the Hengduan Mountains, China. Some dozens of phages were isolated on *Flavobacterium psychrophilum*, a psychrophilic pathogen of fish. In addition, many psychrotrophic or psychrophilic phage isolates have been obtained from refrigerated food sources, e.g., meat, fish and milk products. Water droplets in the clouds may also harbor viruses, as these unique microenvironments remain liquid at temperatures close to -40°C and allow microbial cells to survive and metabolize avoiding vitrification at subzero temperatures. However, very little is known about phages residing in the atmosphere (see the article below).

Atmosphere

Atmospheric phages and their airborne host microbes originate from various terrestrial or aquatic sources, such as sea spray, desert dust, plant litter, snow, or sometimes, human or animal sources. Oceans are the major producers of primary biological aerosol particles, which are also called biological aerosols, referring to airborne viruses, bacteria, archaea, fungi, pollen, spores, or

fragments of different microorganisms. Marine biological aerosols are released from sea surface microlayer to the atmosphere by bubble bursting process and transported further by winds. Various studies have shown that bacteria and phages are enriched in the sea surface microlayer indicating that a large fraction of atmospheric viruses are likely phages. At the airborne state, viruses are considered to be associated with small organic aerosol particles ($< 1 \mu\text{m}$) and due to the relatively small size, atmospheric residence times of viruses are longer compared to bacteria and other cellular organisms.

Terrestrial dust is another frequent source of bioaerosols and it has been found to contain various VLPs with icosahedral heads and different types of tails. Saharan dust is known to cross the Pacific Ocean in a few days' time, indicating that phages attached to small dust particles can indeed travel long distances in air. Terrestrial dust contains a size distribution of inorganic and organic particles with the smallest ones being able to penetrate lung alveoli. This suggests that in addition to various environmental sites, phages can be transported also to the lungs and from therein to the blood circulation of humans and animals. Diverse phages have also been observed in different types of soils and plant litter from which they can be aerosolized by winds.

Because environmental phages are major drivers of the carbon cycles by causing cellular lysis, they can also influence climate change. The changing climate, on the other hand, can affect for instance, phage life cycles. Atmospheric dispersal of phages and other viruses has been considered as one of the most plausible explanations for the major question why genetically similar viruses are found from geographically distant environments, in spite of the enormous number of phages in the oceans (up to 10^{31}). Because phages influence horizontal gene transfer, atmospheric phages can transport genes to host bacteria even to distant environments, affecting the global gene pool. Extremophilic archaeal viruses were found to be transported by air between three different geographically distant hot springs of Yellowstone National Park, suggesting that airborne viral dispersion contributes to local population diversity more than mutation rate. It is likely that the same phenomenon is experienced globally for phages and other viruses as well.

The atmospheric significance of phages and their host bacteria is especially crucial in polar environments, where aerosols from terrestrial origin are less prevalent. Atmospheric microorganisms can function as cloud condensation nuclei and ice nuclei, affecting cloud dynamics. Bacteria, such as those belonging to the genus *Pseudomonas*, are known to contain ice nucleation active membrane proteins. In some rare occasions, phages have also been shown to be able to nucleate ice, but to date very little is known about this property.

Environments like the oceans are known to contain numerous phages that are ecologically important, but to our knowledge, specific phage isolates originating from outdoor atmospheric samples, are yet to be discovered. In addition, very little is known about the survival and infectivity of phages in the atmosphere. At the airborne state, phages are subjected to several environmental stressors, such as intense UV radiation, desiccation, rain, ice formation, and low temperature. Phages can be protected from these stressors for instance by remaining in the prophage state within the host cell. Attachment to solid particles, on the other hand, can protect phages from desiccation caused by UV. Flow cytometric studies of air samples have demonstrated that atmospheric samples contain around 10–100 times more viruses than bacteria and approximately 70% of these viruses are attached to organic aggregates. Deposition rates of approximately $10^9\text{--}7 \times 10^9 \text{ m}^{-2}$ in a day were reported for viruses and $10^7\text{--}8 \times 10^7 \text{ m}^{-2}$ in a day for bacteria with the highest virus deposition rates originating from marine bioaerosols. It is presumable that a large percentage of these viruses are phages.

Conclusions

Although characterized by very challenging conditions, extreme environments are in fact inhabited by a large number of extremophiles, which are mostly microorganisms. Viruses and bacteriophages in particular are abundant and active in extreme environments and have globally important ecological roles. Virus-like particle densities differ in various extreme niches, being e.g., $10^4\text{--}10^5 \text{ VLPs ml}^{-1}$ in the deep-sea and up to $10^9 \text{ VLPs ml}^{-1}$ in hypersaline waters. Tailed VLPs typical for bacteriophages, as well as other more unusual particle morphologies, have been observed in extreme environments. Part of these VLPs may represent archaeal viruses. Metagenomic studies have revealed *Caudovirales*-related sequences in numerous extreme sites. Atmospheric movement of phages has been suggested to provide some explanations for the observed genetic similarity between phages originating from geographically distant extreme environments. Sampling of certain environments, e.g., hydrothermal vents, seabed subsurface or the atmosphere, is still very challenging technically, while other sites, e.g., hypersaline lakes and salterns, represent more easily accessible locations. Subsequently, the number of isolates from different types of extreme environments varies. Known extremophilic phage isolates display the following morphologies: tailless or tailed icosahedral (myo-, siphon-, or podoviruses), spherical, and filamentous. Their genomes are linear or circular ds- or ssDNA molecules, many of which are not yet sequenced. Detailed molecular studies of the obtained isolates are still rare, but the available data adds insights into the understanding of evolutionary relations between different viral groups. The research on extremophilic phages widens our view on global viral diversity and helps to determine certain boundaries of the virosphere.

Glossary

Acidophilic Thriving under highly acidic conditions.

A-form One of the three major forms of double-stranded DNA, with a 23 Å helical diameter and 11 bp per helix turn.

Capsid Protein shell that encloses the genetic material of the virus.

Convergent evolution Independent evolution of similar features in species of different lineages.

Core genes One or more genes strongly conserved at the nucleotide sequence level among a related group of genomes.

Homologous recombination Recombination between two identical or similar DNA sequences.

Hyperthermophilic Requiring extremely high temperatures for optimal growth.

Inverted terminal repeats Short, related or identical sequences located in reverse orientation at the ends of the viral genome.

Jelly-roll fold A protein fold composed of eight β -strands arranged in two antiparallel four stranded β -sheets.

Pleomorphic viruses Viruses with asymmetric or variable virion morphology.

Protein glycosylation Post-translational modification where a carbohydrate molecule is covalently bound to a predetermined region of a protein to form a glycoprotein.

Proviruses Viral genomes integrated into the host chromosome.

Structural genomics Description of the three-dimensional structure of a protein encoded by a given genome.

Synteny The shared ordering of genomic segments along a chromosome.

Thermophilic Requiring high temperatures for optimal growth.

Viral envelope Lipid layer present in many types of viruses that protects their genetic material.

Virion Infectious mature virus particle.

Introduction

One of the most surprising results of the studies on viral diversity on our planet is the observation of an astounding number of different viral morphologies in the habitats where large-scale biodiversity is least expected – in geothermally heated environments where temperatures exceed 80°C and pH values are often below pH 3. Many virus morphologies observed here have never been detected in environments with less extreme conditions. Besides common filamentous and spherical virions, this diversity includes particles resembling bottles, droplets, coils and spindles, which can be tailless, tailed or two-tailed. Viruses with all these morphologies have been isolated from hot terrestrial springs of Europe, Asia, and North America. The hosts for this collection of viruses are archaea from the phylum Crenarchaeota – members of the genera *Acidianus*, *Aeropyrum*, *Metallosphaera*, *Pyrobaculum*, *Stygiolobus*, *Sulfolobus* and *Thermoproteus*. All these hosts grow optimally at temperatures above 80°C and thus are referred to as hyperthermophiles. Viral infection occurs most efficiently at optimal temperatures of host growth and thus also the viruses are considered to be hyperthermophiles.

Table 1 Viruses of Crenarchaeota

Family name	Virion shape	Example of species	Envelope	Genome type and size (bp)	Accession number
Viruses with particular shapes					
<i>Ampullaviridae</i>	Bottle-shaped, with fibers at the blunt end	Acidianus bottle-shaped virus (ABV)	External	Linear dsDNA, 23,900	EF432053
<i>Bicaudaviridae</i>	Spindle-shaped with two appendages	Acidianus two-tailed virus (ATV)	None	Circular dsDNA, 62,730	AJ888457
<i>Clavaviridae</i>	Bacilliform	Aeropyrum pernix bacilliform (APBV1)	None	Circular dsDNA, 5278	AB537968

Hyperthermophilic viruses are extremely thermostable in aggressive environmental conditions of their natural habitats, as well as in the laboratory conditions, e.g., thermal inactivation of some of them requires autoclaving at 121 °C at least for 40 min.

Based on their diverse morphological and genomic properties, the isolated and characterized viruses of Crenarchaeota are currently classified into 13 families (Table 1), 1 order *Ligamenvirales* and 1 proposed class *Tokiviricetes*. The genomes of members of all families, except *Spiraviridae*, have double-stranded (ds) DNA genomes, circular or linear (Table 1), whereas members of the *Spiraviridae* have circular single-stranded (ss) DNA genome.

Morphology and Structure

The families of crenarchaeal viruses have virions with diverse characteristic morphologies. The bottle-shaped, tailed spindle-shaped, tailless spindle-shaped, bacilliform, coil-shaped, droplet-shaped morphologies of members of the *Ampullaviridae*, *Bicaudaviridae*, *Fuselloviridae*, *Clavaviridae*, *Spiraviridae*, and *Guttaviridae*, correspondingly, are unprecedented among viruses of Bacteria and Eukarya, and represent Archaea-specific virion morphotypes. Specific for Archaea are also dsDNA viruses with filamentous virions, including members of the *Lipothrixviridae*, *Rudiviridae* and *Tristromaviridae*, as well as viruses with spherical virions carrying helical nucleoprotein core – members of *Globuloviridae*, *Ovaliviridae* and *Portogloboviridae*. The only family of crenarchaeal viruses with structural resemblance to viruses from other domains of life is *Turriviridae*. Turriviruses have non-enveloped icosahedral virions, with an internal lipid layer enclosing circular dsDNA genome. The major and minor capsid proteins have the double and single jelly-roll fold, respectively, and are related to those found in a wide range of bacterial and eukaryotic viruses. In other studied cases, capsid proteins of crenarchaeal viruses have unique structural folds.

Structures of virions from the families *Clavaviridae*, *Lipothrixviridae*, *Portogloboviridae*, *Rudiviridae*, and *Tristromaviridae*, were reconstructed at near atomic resolution using cryo-electron microscopy (cryo-EM). The results shed light on the mechanisms of virion morphogenesis and provide information on the molecular basis of high thermostability of the corresponding virions. Remarkably, in the reconstructed virions of members of the four latter families the packed dsDNA could be observed and was found to be in A-form: the phosphate-phosphate distance along DNA backbone is about 5.9 Å, as opposed to 7 Å for common B-form DNA. The common occurrence of A-DNA in hyperthermophilic viruses suggests that it may be the prevalent storage form of DNA in most extreme environments.

Most known viruses of Crenarchaeota are covered with envelopes. In those cases, where this was studied, the viruses form envelopes from lipids selectively acquired from the pool of host lipids.

Negative stain with uranyl acetate, except for ACV, which is in vitreous ice. Bars, 100 nm. Image modified from Prangishvili, D., Bamford, D.H., Forterre, P., *et al.*, 2017. The enigmatic archaeal virosphere. *Nature reviews Microbiology* 15, 724–739.

Viruses with particular morphologies

Family Ampullaviridae (from Latin ampulla for “bottle”)

The enveloped virion of Acidianus bottle-shaped virus (ABV), the only isolated member of the family *Ampullaviridae*, resembles in its shape a champagne bottle (**Fig. 1(a)**). It has an overall length of 230 nm and a width varying from 75 nm at the broad end to 4 nm at the pointed end. The broad end of the virion is decorated with 20 thin rigid filaments, which appear to be inserted into a disc and interconnected at their bases. The cone-shaped inner core is formed by a toroidally supercoiled nucleoprotein filament 7 nm in width. It is presently unclear whether the pointed end or the filaments on the broader end are involved in adsorption to the cell surface and channelling of viral DNA into host cells. The virion contains six major proteins in the size range between 15 to 80 kDa.

Family Bicaudaviridae (from Latin bi, “two”, and cauda for “tail”)

The virions of Acidianus two-tailed virus (ATV), the only currently classified member of the family *Bicaudaviridae*, are released from host cells as spindle-shaped particles with overall dimensions of approximately 120×300 nm (**Fig. 1(b)**). Upon further incubation at temperatures above 75°C , appendages protrude from both pointed ends of the virion, and the lemon-shaped virion body shrinks to approximately 85×150 nm. The tails are heterogeneous in length, reaching 400 nm; the maximum length of the virion including tails reaches about 1000 nm. They have a tube-like structure and terminate with a narrow channel, which is 2 nm in width, and a terminal anchor-like structure formed by two furled filaments, each with a width of 4 nm. The virion contains at least eleven proteins with molecular masses in the range of 12–90 kDa.

Extracellular morphological development of the ATV virion takes place specifically at temperatures above 75°C , close to that of the natural habitat, and does not require the presence of host cells, an exogenous energy sources or specific co-factors. However, the mechanism of development of the ATV tails remains unknown.

Family Clavaviridae (from Latin clava for “club”, “stick”)

Aeropyrum pernix bacilliform virus 1 (APBV1), the only known member of the family *Clavaviridae*, has non-enveloped bacilli-form, rigid virions with dimensions of about 143×16 nm (**Fig. 1(c)**). The terminal cap structures, one of which is pointed and the other rounded, most likely are involved in DNA packaging and recognition of the host cell.

The virions carry multiple copies of a single major capsid protein (MCP) of about 10 kDa and three minor capsid proteins which have molecular masses in the range of 9.5–21.5 kDa. The MCP consists of two α -helices linked with a β -hairpin, a structural fold not seen in the capsid proteins of other known viruses. The structure of APBV1 virion was determined by cryo-electron microscopy at near-atomic resolution. The structure reveals how the MCPs pack together forming a tubular structure: each MCP molecule makes extensive hydrophobic contacts to six other neighbouring subunits, forming very tight hydrophobic interface which apparently contributes to the virion stability at extremely high temperatures. The inner surface of the tubular structure is positively charged, allowing efficient interactions with the circular dsDNA genome and its packaging as a left-handed superhelix. The structure allowed to propose an assembly model where the dsDNA genome and the capsid assembly in a concerted fashion. According to this model, the virion assembly starts by binding of three specific sites of the circular dsDNA with one of the cap structures; this forms three loops, which gradually intertwine directed by protein assembly into the tubular structure; after all DNA has been covered by protein, the open end of the virion is sealed by another cap structure.

Family Fuselloviridae (from Latin fusello for “little spindle”)

Virions of this family are enveloped and many have the shape of a lemon or spindle, with a bunch of thin filaments attached to one of the two pointed ends (Fig. 1(d)). Other family members are more pleomorphic and elongated, with three relatively thick filaments at one pointed end. The terminal filaments most likely are involved in adsorption to the host cell surface. Virions have dimensions of approximately 60×100 nm. The envelope of *Sulfolobus* spindle-shaped virus 1 (SSV1) contains lipids and proteins VP1 and VP3. The circular dsDNA of SSV1 is positively supercoiled when isolated from virions.

Examination of the SSV1 virion using cryo-electron microscopy (cryo-EM) have provided only limited information on virion architecture, but the study of SSV1 virion assembly and egress using electron tomography was more informative. Both virion assembly and egress were found to be concomitant and occur at the cellular cytoplasmic membrane via a process highly reminiscent of the budding of enveloped viruses that infect eukaryotes, including human immunodeficiency virus, influenza virus, and Ebola virus.

Family Guttaviridae (from Latin gutta for “droplet”)

The guttaviruses have slightly pleomorphic enveloped virions. Virions of *Sulfolobus* neozelandicus droplet-shaped virus (SNDV) resemble elongated droplets with varying dimensions, 110–185 nm in length and 95–70 nm in width (Fig. 1(e)). The pointed end of the virion is covered by a beard of thick filaments. Virions of another member of the family, *Aeropyrum* pennix ovoid virus 1 (APOV1), are ovoid without detectable filamentous attachments.

Family Spiraviridae (from Latin spira for “coil”)

The virions of *Aeropyrum* coil-shaped virus (ACV), the sole member of the family, are hollow, non-enveloped cylindrical particles, measuring about 230×20 nm. A short appendage of about 20 nm protrudes from each end of the cylindrical virion (Fig. 1(f)). Exceptionally, the viral genome is a single-stranded, positive-sense DNA molecule. The virion carries two MCPs with molecular masses of about 23 and 18.5 kDa, and a few minor virion proteins. The observation of partially degraded virions enabled to propose the following model of virion morphogenesis: the circular ssDNA is covered by multiple copies of the MCP and the two halves of the circular nucleoprotein filament intertwine to form a rope-like structure, which is further condensed into a helix of higher order.

Spherical viruses

Family Globuloviridae (from Latin globulus for “small ball”)

The virions of globuloviruses are enveloped, spherical particles, 70–100 nm in diameter (Fig. 2(a)). On the surface of the virion are multiple spherical protrusions about 15 nm in diameter. The viral envelope contains host-derived lipids and encases a tightly-packed superhelical nucleoprotein consisting of linear dsDNA and multiple copies of 33 kDa MCP. The virions carry minor capsid proteins. Virions of *Thermoproteus* spherical piliferous virus 1 (TSPV1) are decorated with numerous highly unusual filaments, which can extend hundreds of nanometers from the virion.

Family Ovaliviridae (from Latin ovalis for “oval”)

The sole known member of the *Ovaliviridae* family, *Sulfolobus* ellipsoid virus 1 (SEV1), has virions of ellipsoidal shape which measure about 115×80 nm. The virions are enveloped by a lipid containing membrane. The membrane encases circular nucleoprotein filament - consisting of circular dsDNA and DNA-binding MCPs, wrapped multiple times around the central axis of the virion (Fig. 2(b)).

Family Portogloboviridae (from Latin porto for “to bear”, and globus for “ball”)

The virions of *Sulfolobus* polyhedral virus 1 (SPV1) are icosahedral, about 90 nm in diameter (Fig. 2(c)). The cryo-EM reconstruction of the virion revealed structural details at near-atomic resolution. The icosahedral capsid is formed by 2 types of MCPs both of which carry variants of the single jelly-roll fold and are arranged in an atypical manner. The protein capsid encloses an internal lipid-containing membrane, which, in turn, encloses a spherical core formed by a circular nucleoprotein filament consisting of dsDNA and DNA-binding MCP. In the circular nucleoprotein, the dsDNA is complexed by a dimeric DNA-binding MCP

and is in A-form. The condensation of the circular nucleoprotein into a spherical core is suggested to occur in two steps: folding of circular nucleoprotein into a raft which is then spooled into concentric shells.

Family Turriviridae (from Latin turris for “tower”)

The overall morphology of non-enveloped icosahedral virions of the *Turriviridae* is highly similar to that of bacterial viruses from the families *Tectiviridae* and *Corticoviridae*: the virions are icosahedral with an inner lipid layer and pack naked dsDNA with the help of virus-encoded ATP-dependent molecular machinery (Fig. 2(d)). Moreover, members of all three families share the structure of MCPs which exhibit the double-jelly roll fold. Cryo-EM reconstruction of *Sulfolobus turreted icosahedral virus* (STIV) revealed unique structural features, including the elaborate turret-like structures at the fivefold vertices and the unusual pseudo- $T = 31$ icosahedral lattice on which the virion is built.

Filamentous viruses

Proposed class Tokiviricetes: order Ligamenvirales: family Rudiviridae (from the Latin rudis for “small rod”) order Ligamenvirales: family Lipothrixviridae (from the Greek lipos for “fat” and thrix for “hair”) family Tristromaviridae (from the Greek tria for “three” and stroma for “layer”)

The virions of members of the three families of the proposed class *Tokiviricetes* are filamentous, about 23 nm in width and the lengths in the range of 400–2000 nm, depending on the size of the linear dsDNA genomes and parameters of the nucleoprotein helix (Fig. 3). At both ends, the virions carry identical terminal structures. In the case of *Acidianus filamentous virus 1* (AFV1), a member of the *Lipothrixviridae*, the terminal structure resembles claws and folds upon interaction with the appendages of the host cells (Fig. 3(a)). The virions of *Sulfolobus islandicus* rod-shaped virus 2 (SIRV2), the type member of the *Rudiviridae* family, are decorated with three thin terminal fibers, whereas virions of *Pyrobaculum filamentous virus 1* (PFV1), a member of the *Tristromaviridae*, possess bundles of filaments that can reach a length of 80 nm (Fig. 3(b) and (c)).

The virion structures of members of the three families have been reconstructed by cryo-EM at near atomic resolution and revealed similar, previously unknown form of virion organization. In all three families the core of the filamentous virion is a tube-like nucleoprotein formed by condensation of linear dsDNA by dimers of the MCPs – homodimers in case of *Rudiviridae* and heterodimers in the case of the other two families (Fig. 4(a)). As a result of binding to DNA, the MCPs form a helix-turn-helix structure and tightly

wrap around dsDNA, in a manner not observed in known viruses, and transforms it into A-form (Fig. 4(b)). Such arrangement keeps DNA inaccessible for solutes and ensures virion stability in highly aggressive environmental conditions. The MCPs have a molecular mass of about 14.5 kDa. *Rudiviridae* encode a single MCP, whereas each of the two other families encodes two paralogous MCPs. Remarkably, although the MCPs from the three virus families do not share significant sequence similarity, their structures are highly similar – they all carry unique four-helix bundle fold, not seen in the capsid proteins of other known viruses. The structural similarity of the MCPs suggests common origin of the MCPs and provides arguments to postulate evolutionary relationship between the three virus families which employ these MCPs. Thus, it was proposed to unify the families *Rudiviridae*, *Lipothrixviridae*, and *Tristromaviridae* into the new virus class *Tokiviricetes*. The former two families reveal certain similarity also at the genomic level, suggesting closer relationship. Thus, *Rudiviridae* and *Lipothrixviridae* were unified also in a taxon of a lower rank, the order *Ligamenvirales*.

The major difference in virion architecture of the three families concerns coating of the nucleoprotein core. In the *Rudiviridae*, it is non-enveloped, in *Lipothrixviridae*, covered with lipid envelope, and in *Tristromaviridae*, covered by a protein matrix which mediates contact with the outer lipid envelope. The matrix layer of the *Tristromaviridae* is formed by an 18 kDa capsid protein, VP3. As in other crenarchaeal viruses, *Lipothrixviridae* and *Tristromaviridae* recruit the lipids for formation of the envelope from the pool of host lipids.

The thickness of the lipid envelope in the reconstructed virions of the lipothrixviruses is about 20–25 Å, only half of the thickness of the cellular membrane. The host membrane, as in all Crenarchaeota, represents a 40 Å monolayer of glycerol dibiphytanyl glycerol tetraether (GDGT) lipids with different numbers of cyclopentane rings. Studies on the composition and structure of the virion envelope showed that the virus selectively acquires more flexible GDGT lipids lacking cyclopentane rings, which can be bent into U-shaped, ‘horseshoe’ conformation, forming the 20 Å thick virion envelope. Apparently, the membrane with lipids in such conformation, which was previously never observed in the living world, has advantages for survival in aggressive conditions of the natural environment of the hyperthermophiles.

General comments

Summarizing the results on studies on morphology and morphogenesis of viruses of hyperthermophilic Crenarchaeota, it could be noted that packaging of viral genomes in the form of a nucleocapsid appears to be the major structural characteristic of crenarchaeal viruses. Based on the available information, the assembly of the virion core apparently occurs through concerted coating of the DNA with MCPs and spontaneous self-assembly of such nucleocapsids into minimum free energy structures of different shapes. The self-assembly pathway of virion morphogenesis is common for RNA viruses but not for dsDNA viruses, where capsid assembly and genome packaging are generally separated. dsDNA viruses of Bacteria, herpesviruses of Eukarya, and crenarchaeal *Turritoviridae* pack dsDNA in the naked state into the pre-assembled empty capsids. This process requires significant energy expenses — mainly because of the mutual repulsion of the negatively charged phosphate backbone of the DNA — and is facilitated by virus-encoded elaborate molecular machinery. Considering the complexity of such process, it is surprising that the pathways of virion morphogenesis which are common for crenarchaeal viruses are so rare in the world of dsDNA viruses.

In most crenarchaeal virus families, the nucleoprotein core is covered by lipid-containing envelopes. Moreover, the core of the *Portogloviridae* is encased by an icosahedral protein shell. The mechanisms of coating of the nucleoprotein cores remain

unknown. For *Fuselloviridae*, the final step of virion assembly was shown to occur in the course of budding from the host cell in a process, resembling the morphogenesis of enveloped viruses of eukaryotes. For other crenarchaeal viruses, the coating of virions with a lipid envelope takes place apparently intracellularly.

Genomes

The genomes of crenarchaeal viruses are generally small in size (Table 1), with the largest ones (60–70 kb) being found in members of the family *Bicaudaviridae*. The 5,278 bp-long genome of the clavavirus APBV1 is among the smallest known dsDNA genomes. The other record holder is the coil-shaped spiravirus ACV – its ssDNA genome with 24.9 kb is the largest among known ssDNA genomes. The genomes can be either circular or linear (Table 1). Viruses with linear genomes often carry inverted terminal repeats (ITRs) of different length and exploit different strategies to protect their genome termini, such as covalently closed hairpins or covalently attached terminal proteins.

Along with the extraordinary diversity of morphotypes, another outstanding feature of archaeal viruses is the uniqueness of their genome content, with a very low proportion of genes with recognizable homologs in public databases. Indeed, family-specific comparison of viral proteomes against the sequence databases revealed that ~85% of the crenarchaeal virus proteins do not have identifiable homologs when an E-value threshold of $< 1e-5$ is used.

Functional annotation of crenarchaeal proteins shows that very few of these proteins are homologous to any sequences in the public databases, be it proteins of other viruses or those of cellular organisms. Consequently, archaeal virus genomes remain a rich source of unknown genes, many of which could be responsible for unique mechanisms of virus-host interactions or possess unexpected properties.

Structural genomics have been performed to promote the functional characterization of *Fuselloviridae*, *Bicaudaviridae*, *Rudiviridae*, *Lipothrixviridae*, *Globuloviridae* and *Turriviridae* proteins. Protein structures were determined by X-ray crystallography, and nuclear magnetic resonance (NMR) spectroscopy. For some viral proteins, the structures displayed unique folds with no homologs in databases, hindering the assignment of putative functions. In few cases, the structural information suggested a function which was verified biochemically. This was the case, e.g., for a novel type of nuclease encoded by the lipothrixvirus AFV1 and replication initiator protein encoded by the rudivirus SIRV2.

Notably, none of the viruses encodes a recognizable DNA-dependent RNA polymerase and only members of two families – *Ampullaviridae* and *Ovaliviridae*, encode recognizable DNA-dependent DNA polymerases. However, crenarchaeal viruses commonly encode multiple transcription factors which may recruit and redirect the host transcription machinery to preferential expression of viral genes.

Comparative genomic analyses have revealed that hyperthermophilic viruses from different families share just a small group of common genes, suggesting independent origins of the distinct groups of archaeal viruses. Ten virus families each have only one or two members with the sequenced genome. Exceptions are *Fuselloviridae* and two families of the order *Ligamenvirales* with higher number of members with sequenced genomes. Comparison of these genomes facilitated functional predictions and contributed to understanding the evolutionary history of the corresponding virus families, and will be briefly detailed below.

Family *Fuselloviridae*

The genomes of all members of *Fuselloviridae* are highly similar at the nucleotide sequence level and display overall gene synteny. A high frequency of homologous recombination has been reported between family members. The majority of predicted ORFs of the fuselloviruses cannot be assigned a function based on homology with sequences in public databases. Comparison of genome sequences has revealed a set of 12 not contiguous “core” genes shared by all family members, suggesting a common evolutionary history despite differences in the geographical context. The “core” proteome includes structural proteins, predicted DnaA-like AAA + ATPase, transcriptional regulators and a tyrosine superfamily integrase, which is involved in the integration of the viral genome into the host tRNA gene. Accordingly, the infected cell cultures contain both the covalently closed circular form of the viral genome and the integrated provirus. Unlike in the case of temperate bacteriophages, the integrase gene of the fuselloviruses is partitioned into two fragments upon the viral genome integration. Notably, studies on the prototypical fusellovirus SSV1 have shown that SSV1 integrase is not essential for the viral cycle. Moreover, nearly half of the predicted SSV1 ORFs were shown to tolerate insertions or deletions without affecting the viral infectivity.

Order *Ligamenvirales*

All members of the order have linear dsDNA genomes. On the example of the genome of the rudivirus SIRV1 it was shown that the two strands of the linear dsDNA genomes are covalently linked at both ends, forming a continuous polynucleotide chain and producing terminal hairpin structures. For other ligamenviruses such detailed analysis of the terminal regions has not been performed. Rudiviruses carry terminal inverted repeats which differ in size and sequence. The longest with 2 kb is found in the rudivirus SIRV1. In both rudiviruses and lipothrixviruses active genome remodelling, involving both deletions and horizontal acquisition of new genes, has been documented. The comparison of the genomes of different members of the same family and different strains of the same species revealed multiple examples of genomic rearrangements caused by insertion/deletion of

sequences that do not disrupt the ORFs. In *Rudiviridae* and *Lipothrixviridae* such sequences were shown to carry 12 bp or multiples thereof. It was suggested that the latter might constitute genetic elements mobilized by archaeal intron splicing.

Members of the *Rudiviridae* share significant similarity in the genome sequence and synteny, and carry a set of conserved core genes, most of which are localized in the middle region of the linear genome. By contrast, the genomes of *Lipothrixviridae* display a considerable variation in gene order and content, suggesting a longer evolutionary history. Based on the sequence similarity, the genomes of *Lipothrixviridae* group into four clusters of related species which form the four genera in the family. The examples of intergenomic recombination have been observed between members of different genera.

Properties of about half of the proteins encoded by the rudiviruses SIRV1 and SIRV2 have been predicted as a result of analysis of their sequences, structures and biochemical characteristics. Such proportion of recognized gene functions is among the highest for crenarchaeal viruses. The proteins with predicted functions include transcription regulators with ribbon-helix-helix and helix-turn-helix motifs, glycosyltransferases, acetyltransferase, Holliday junction resolvase, methyltransferase, dUTPase, ssDNA-binding protein, ssDNA annealing ATPase, Cas4-like exonuclease, as well as a protein specifically interacting with the host proliferating cell nuclear antigen (PCNA) and presumably recruiting it for the replication of the viral genome. Moreover, three proteins of the virus SIRV2 have been identified as anti-CRISPR proteins, which inhibit type I and type III CRISPR-Cas immunity systems of the *Sulfolobus* host. Detailed studies on the life cycle of the rudivirus SIRV2 enabled identification of the viral protein involved in the unique mechanism of virion egress. The function of this protein could not be predicted based on its sequence and was verified only as a results of detailed studies on the virus life cycle, supporting the possibility that many genes of archaeal viruses are implicated in specific aspects of virus-host interactions.

Evolutionary relationships

The unique morphological and genomic features of crenarchaeal DNA viruses raise important questions regarding their origins. The analysis of the evolutionary relationships between all dsDNA viruses using the bipartite network approach, which traces connections between viral genomes through shared gene families, revealed that crenarchaeal viruses are largely disconnected from the global dsDNA virosphere. The families of crenarchaeal viruses are themselves largely disconnected from each other and share just a small group of common genes, suggesting that most families of crenarchaeal viruses have evolved independently of one another.

How and when did archaea-specific viruses originate? Why do they only infect archaea? There are at least two non-mutually exclusive explanations. Some of the archaea-specific virus groups could have emerged during the early stages of cellular evolution and been retained in the Archaea but lost in the domains Bacteria and Eukarya. Other archaeal virus groups could have evolved concomitantly with the Archaea or, even more recently, within specific archaeal lineages. The observed limited gene sharing between different groups of archaea-specific viruses seems to make the latter possibility particularly plausible.

ICTV International Committee on Taxonomy of Viruses

kbp Kilo base pairs

knt Kilo nucleotides

MCP Major capsid protein

nt Nucleotide

ORF Open reading frame

ss Single-stranded

T Triangulation number

Glossary

Alkaliphilic Having a requirement for an environment with high pH.

Circular permutation A change in the sequence of the linear DNA termini that does not alter the relative sequence (e.g., circular permutation of ABCDEFGH could generate BCDEFGHA, CDEFGHAB, etc).

Concatamer Two or more DNA molecules that are linked together to form a long, linear DNA molecule.

Halophilic Having a requirement for an environment with a high salt concentration.

Headful packaging The mechanism of packaging viral DNA based on the size of the virus head, rather than the length of the viral genome.

Integrase An enzyme which can integrate viral DNA into the genome of its host cell.

Lysogen A host cell that has been infected by a virus that remains dormant, despite the presence of viral DNA.

Methanogenic Having the ability to produce methane.

Prophage A virus that is dormant within the host cell either integrated into the host chromosome or replicating free like a plasmid.

Protein-primed DNA replication Duplication of a linear DNA genome being started via the interaction of DNA polymerase with a protein covalently linked to the DNA termini.

Temperate virus A virus that is able to infect a host, but remains dormant within the host cell.

Thermophilic Having a requirement for an environment with high temperature.

Virion Infectious mature virus particle.

Virulent virus A virus that is able to infect a host, replicate, and subsequently leave the host cell by lysing the host cell.

Introduction

Microorganisms belonging to the phylum *Euryarchaeota* inhabit diverse environments: halophilic euryarchaea dominate in hypersaline environments such as solar salterns and salt lakes, methanogenic euryarchaea are found in intestines, anoxic sediments, and sludge digesters, while thermophilic euryarchaea thrive in thermal environments, e.g., hot springs and deep-sea hydrothermal vents. Euryarchaea are also abundant and active in oceanic surface waters.

The first archaeal virus Hs1 of halophilic euryarchaeon *Halobacterium* was found in 1974, being originally described as a bacteriophage before it was recognized that Archaea and Bacteria form two different domains of life. During the last 10 years, the number of described euryarchaeal viruses has tremendously increased due to extensive virus surveys, especially by using samples from hypersaline environments. Today, more than 110 euryarchaeal virus isolates or virus-like particles (VLPs) are described. Euryarchaeal viruses are extremely diverse, having various virion morphologies, genome types, sequences, life cycles, and host ranges. Among the five different morphologies known for euryarchaeal viruses ([Fig. 1](#)), tailed icosahedral viruses form the most numerous group with all three tail types found in tailed dsDNA bacteriophages of *Caudovirales*. Other known morphologies are tailless icosahedral viruses with internal membrane, pleomorphic, spindle-shaped, and spherical viruses. The smallest euryarchaeal virus is the pleomorphic virus HRPV-1 with a diameter of 40 nm, while the largest capsid diameter is found in tailed icosahedral virus HHTV-1 (~95 nm).

So far, all known archaeal viruses have genomes of either linear or circular double-stranded (ds) or single-stranded (ss) DNA molecules. Euryarchaeal pleomorphic virus HRPV-1 was the first described archaeal virus with a ssDNA genome, but most of the euryarchaeal viruses known today have a linear dsDNA genome. The genome sizes range from 7,048 nucleotides (nt) of *Halorubrum* pleomorphic virus HRPV-1 to 143,855 kilo base pairs (kbp) of *Halogrammon* tailed virus HGTV-1. For ~50 euryarchaeal virus isolates, the whole genome sequence is available ([Tables 1–3](#)). Currently, euryarchaeal viruses are classified by the International Committee on Taxonomy of Viruses (ICTV) into the families *Sphaerolipoviridae*, *Pleolipoviridae*, and the newly proposed family *Halspiviridae*, but there is also a significant number of unclassified ones. High number of proviruses found in the chromosomal

^aMorphotypes P, L, and S correspond to pleomorphic, lemon-shaped (spindle-shaped), and spherical morphologies. Diameter (for P and S) or length and width (for L) are given (nm). Nd, not determined.

^bL, linear; C, circular.

sequences of euryarchaea and metagenomic datasets indicate that the viruses known today represent only a minuscule fraction of the true euryarchaeal viral diversity. Here, we review advances in understanding viruses infecting euryarchaea by summarizing the data from culture-independent studies and describing known virus isolates.

Icosahedral Tailed Viruses

To date, about 90 euryarchaeal icosahedral tailed viruses have been isolated, the majority of which are viruses infecting halophilic archaea of the class Halobacteria and the rest infect methanogenic archaea belonging to the family *Methanobacteriaceae* (Table 1). Archaeal tailed viruses morphologically resemble bacteriophages of the order *Caudovirales*, with an icosahedral head and either a long contractile (myovirus) or non-contractile (siphovirus) tail or a short non-contractile tail (podovirus) (Fig. 1(A)-(C)). Of these three morphotypes, myovirus isolates are the most numerous, while only one archaeal podovirus HSTV-1 of *Haloarcula sinaiensis* is known. All currently known euryarchaeal icosahedral tailed viruses have dsDNA genomes (Table 1), which are reminiscent to the genomes of tailed bacteriophages in the order *Caudovirales*. Tailed archaeal viruses resemble tailed bacteriophages by a modular structure and mosaicism of their genomes, although many ORFs have no assigned functions. The gene for the large terminase subunit is one of the most conserved genes in tailed dsDNA phages and it is annotated in all euryarchaeal tailed virus genomes

described to date. Most archaeal viruses have not been taxonomically assigned to any taxa, except some of the oldest isolates, e.g., phiH, Hs1, and HF2, but obvious similarities with tailed dsDNA phages suggest that all archaeal tailed viruses could be members of the order *Caudovirales*, but having their own family level taxa. Notably, no tailed viruses have been yet isolated for crenarchaeal hosts, although microscopic and metagenomics studies of hyperthermic environments, where crenarchaea typically dominate, have revealed the presence of tailed VLPs and sequences related to phages of *Caudovirales*.

Icosahedral Tailed Viruses of Halophilic Euryarchaea

Since the discovery of the first archaeal virus Hs1 in 1974, other tailed halophilic archaeal viruses have been isolated: Ja1 (1975), B10 (1982), phiH (1982), Hh-1 and Hh-3 (1982), S45 (1984), phiN (1988), S5100 (1990), HF1 and HF2 (1993), phiCh1 (1997), S41, S50.2, and S4100 (1998). From these viruses, only a few have been characterized at the molecular level, and some of the early isolates have been lost later. In 2000s, a few more tailed haloarchaeal viruses have been reported: BJ1 (2007), HHTV-1, HRTV-1, and HCTV-1 (2009). Two large virus surveys of hypersaline environmental samples published in 2012 and 2015 yielded close to 60 new tailed archaeal virus isolates infecting halophilic strains of the genera *Haloarcula* or *Halorubrum* and one *Halogramma* tailed virus. The most recently described isolates are ChaoS9 and HFTV1 (2019), of which HFTV1 represents the first virus infecting *Haloferrax* strain. In addition, several putative proviruses related to tailed viruses have been detected in the genomes of halophilic archaea, showing their wide distribution.

One of the earliest euryarchaeal virus isolates is the temperate myovirus phiH, which was obtained from a spontaneously lysed culture of *Halobacterium salinarum* strain R1. It was actively studied until late 1990s, when the work on this virus isolate stopped due to its genomic instability. phiH virion displays a typical myovirus morphotype and it requires high salt concentrations (3 M KCl or NaCl) for stability. The linear dsDNA genome of phiH is packaged into viral particles, but is a circular plasmid-like molecule in infected cells. Viral DNA is terminally redundant and partially circularly permuted, being packed by a headful mechanism. Recently, the genome of phiH1, a predominant variant of phiH, has been fully sequenced and the annotation has been refined (Table 1). During replication rounds, a mixture of genetically rearranged phiH variants is produced due to the activity of insertion sequences. A so-called L-segment, flanked by insertion sequence(s), may undergo inversions or circularize into an autonomous 12-kbp plasmid phiHL, which provides partial immunity from the phiH infection. phiH1 has been largely used in molecular studies of archaeal gene expression and regulation, resulting in e.g., development of transfection methods in archaea.

Another temperate myovirus, phiCh1, has been isolated from a spontaneously lysed culture of haloalkaliphilic *Natrialba magadii* (Table 1). Despite having very different hosts, phiCh1 is closely related to phiH. Peculiarly, in addition to viral DNA, phiCh1 virions contain several host-derived RNA species of 70–800 nt in length. Unlike phiH, phiCh1 integrates into the host's chromosome. The replicative form is circularly permuted and terminally redundant, implying a headful mechanism of packaging. phiCh1 genome of 58,498 bp is methylated and arranged into three transcriptional units. phiCh1 and phiH1 genomes display similar gene synteny and share 63% nucleotide identity. Similarly to phiH1, phiCh1 demonstrates genomic rearrangements. The rearrangements caused by the lambda-like integrase Int1 result in the inversion in the region of two genes encoding putative tail fiber proteins, which affects host recognition specificity. Genomic rearrangements have been also suggested in haloarchaeal myoviruses S41 and S50.2 of *Hbt. salinarum* and siphovirus BJ1 of *Halorubrum*.

A myovirus related to phiH and phiCh1, ChaoS9, has been recently isolated after a spontaneous lysis of a *Hbt. salinarum* culture. The left-end region (first 25 kbp) of ChaoS9 genome (Table 1) shares similarities in sequence and gene synteny with phiCh1 and phiH, while the right end (from 25 to 55 kbp) is significantly more divergent. The viruses share overall nucleotide identity of over 74%. The left-end region of ChaoS9 carries tail fiber genes, which are similar to those in phiCh1 and phiH, and other structural proteins, while the right-end region encodes proteins involved in DNA replication and lysogeny. ChaoS9 major capsid protein (MCP) displays 36% amino acid identity to that of siphovirus HHTV-1 of *Haloarcula hispanica*. Putative head and assembly proteins are unrelated in ChaoS9, phiH, and phiCh1. The revealed similarities in tail morphogenesis module and differences in head morphogenesis module suggest that large recombination events may have shaped the genomes of these viruses. This kind of genomic plasticity is also typical for tailed bacteriophages of the order *Caudovirales*.

One more example of two closely related haloarchaeal tailed viruses is HF1 and HF2, both isolated from Cheetham Saltworks in Victoria, Australia. These myoviruses are virulent, displaying particles of a similar size and genomes of a similar length (76–77 kbp). Both viruses may enter unstable carrier states, when viruses are produced continuously, but eventually switch to a complete lysis. However, HF1 and HF2 have distinct host ranges with no common hosts. HF1 and HF2 genomes are almost identical in their first 48 kbp, while the right-end regions are 87% identical. Such genomic structure may be a result of a recent recombination event with some other HF-related virus. The divergent right-end part of virus genomes probably contains late genes, encoding viral structural proteins, possibly explaining different host ranges of these viruses. Virus genomes are mosaic and encode own DNA polymerases.

In the first half of the 2010s, global sampling of hypersaline environments resulted in the isolation of dozens of new tailed haloarchaeal viruses. It has been shown that tailed haloarchaeal viruses are able to infect host strains originating from geographically very distant sites or from the same location sampled over a few years. Some of these viruses can also infect strains belonging to different genera. Some myoviruses isolated from the Samut Sakhon solar saltern, Thailand, have shown notably wide host ranges, while some of *Halorubrum* strains from the same location were highly susceptible to virus infections.

A few tailed euryarchaeal viruses have been structurally characterized using cryo-electron microscopy (EM) and 3D image reconstruction. The most detailed structure (~9 Å resolution) has been resolved on HSTV-1, which is so far the only known archaeal podovirus (Table 1). *Haloarcula sinaiiensis* virus HSTV-1 is virulent, and its infectivity depends on salinity. At low salinity,

HSTV-1 is reversibly non-infectious, regaining its infectivity when transferred back to high salinity. This kind of characteristic is very advantageous in environments with salinity fluctuations, caused by e.g., changing weather conditions. The majority of HSTV-1 ORFs have no assigned functions, while other ORFs are similar to those involved in DNA replication and nucleotide metabolism or virion assembly in tailed bacteriophages. The order of genes encoding structural proteins is also same as observed in bacteriophage counterparts. HSTV-1 particles display an icosahedral head with a diameter of 560 Å measured facet to facet and 624 Å vertex to vertex (Fig. 2(A) and (B)). The short podovirus-like tail with base plate tail fibers functions in host recognition. The capsid is decorated with 20 large (at least 138 Å long and 74 Å wide), cone-shaped towers, which are located at positions of threefold symmetry (Fig. 2(B)). The capsid shell is 20 Å thick and is arranged into $T = 7$ laevo lattice. HSTV-1 MCP adopts the bacteriophage HK97 fold (Fig. 2(C)), thus suggesting evolutionary links between archaeal and bacterial tailed viruses and eukaryotic herpesviruses, all having the common HK97 fold in their MCPs. The structural similarity between different viral MCPs (without having any sequence similarity) unites these diverse viruses into one of the structure-based viral lineages (HK97-like viruses). In addition, based on homology modeling, phiCh1 MCP could also adopt the HK97 fold. Most probably, all archaeal tailed viruses share the same conserved HK97 fold to build up their capsids.

The other structurally characterized tailed viruses are siphovirus HVIV-1 of *Haloarcula vallismortis* and myovirus HSTV-2 of *Halorubrum sodomense*. Like podovirus HSTV-1, the infectivities of HVIV-1 and HSTV-2 are reversibly lost in low-salt conditions. Both viruses are virulent with quite long intracellular phases: cells are lysed after 10–12 h of infection. HVIV-1 virion consists of an icosahedral capsid enclosing the linear genome of 101,734 bp and a tail typical for siphoviruses – long and flexible (Table 1). Cryo-EM revealed that the icosahedral capsid of HVIV-1 is arranged into $T = 13$ lattice and decorated with five-fold symmetric spikes at vertices and trimeric decorative structures at the center of each MCP hexamer. HSTV-2 genome (Table 1) shares ~70 and ~60% of overall nucleotide identity with HF1 and HF2 genomes, respectively. HSTV-2 capsid (Table 1) is arranged into $T = 7$ lattice being smaller than

Fig. 2 Structure of the haloarchaeal podovirus HSTV-1 head based on cryo-EM and icosahedral reconstruction, where the tail is invisible. (A) Central section of the icosahedral reconstruction of HSTV-1 is shown viewed along an icosahedral twofold symmetry axis (ellipse). Threefold (triangle), and fivefold (pentagon) symmetry axes are indicated. Bar is 10 nm. (B) 3D isosurface representation of HSTV-1. (C) Bacteriophage HK97 MCP fold (Protein Data Bank code 1OHG). (D) Averaged density showing the MCP fold of HSTV-1 calculated from the six segmented subunits from one HSTV-1 MCP hexamer. HK97 MCP fold (red ribbon) and HSTV-1 MCP fold (blue ribbon) fitted into the EM density in gray (see Panel B). Reproduced from Atanasova, N.S., Bamford, D.H., Oksanen, H.M., 2015. Haloarchaeal virus morphotypes. *Biochimie* 118, 333–343 with a permission from Elsevier.

Fig. 3 Genomic comparisons of the 17 haloarchaeal tailed viruses with completely sequenced genomes. All viruses with complete genome sequence can be found in [Table 1](#). (A) Dotplot alignment of the genomes. (B) Circular visualization of the homologous proteins shared between the selected virus representatives from each of the delineated groups and singletons (myoviruses in blue; siphoviruses in pink; podoviruses in purple). The outermost circle represents the genome maps with the coordinates (kbp) followed by the ORFs (on positive strand in green; on negative strand in red). Putative homologs (sharing over 30% identity) are connected by a gray line. Reproduced from Senčilo, A., Roine, E., 2014. A glimpse of the genomic diversity of haloarchaeal tailed viruses. *Frontiers in Microbiology* 5, 84.

that of HVTV-1. Minor trimeric proteins between the MCPs at the local three-fold positions stabilize the capsid, allowing enlargement of HSTV-2 capsid and fitting of a larger genome, which is a novel strategy not previously observed in virus capsids.

Up to date, from the isolated haloarchaeal tailed viruses, 20 have completely sequenced genomes ([Table 1](#)). In addition, the Genbank database contains a record of CGphi46 virus genome sequence. Based on the description available in Genbank, CGphi46 infects *Halorubrum* sp. and was isolated from Cargill Saltern, USA. The genome is a linear dsDNA of 39,784 bp, displaying similarities to tailed haloarchaeal virus sequences, such as *Halorubrum* virus BJ1. Generally, the genomes of haloarchaeal tailed viruses are dsDNA molecules ranging in length roughly from 32 kbp (HSTV-1) to 144 kbp (HGTV-1) with GC content typically similar to that of their hosts. Some conserved bacteriophage genes, such as for the large terminase subunit, are widely found in haloarchaeal tailed virus genomes, while the majority of predicted ORFs have no assigned functions. Based on the whole genome sequences, a few groups of similar viruses can be distinguished: (1) HF1, HF2, HRTV-5, and HRTV-8, (2) HRTV-7 and HSTV-2, (3) HCTV-1, HCTV-5, and HVTV-1, while other viruses are so far singletons ([Fig. 3](#)). Clearly, many more sequences are needed to gain more insights into genetic diversity of tailed archaeal viruses and their taxonomy and to resolve their relatedness to other viral groups.

Tailed Viruses of Methanogenic Euryarchaea

Since 1980s, several viruses infecting methanogenic archaea have been reported: PG (1984), PMS1 (1986), psiM1 and psiM2 (1989), phiF1 and phiF3 (1993), and Drs3 (2018). In addition, tailed VLPs have been found associated with *Methanococcus voltae* PS. Icosahedral VLPs with long contractile or non-contractile tails (myoviruses and siphoviruses) have been found in high abundances in acetate-fed anaerobic digester sludge reactors dominated by *Methanosaeta*. High numbers of VLPs, including tailed ones, have also been reported in other anaerobic digesters inhabited with methanogens. Moreover, several proviruses have been identified in the genomes of methanogenic archaea belonging to the orders *Methanobacteriales*, *Methanococcales*, and *Methanosarcinales*.

Siphovirus psiM1 was isolated from an anaerobic sludge digester (55–60°C) on *Methanothermobacter marburgensis* ([Table 1](#)). Circularly permuted and terminally redundant linear genome of psiM1 is packaged from a concatemeric precursor via a headful mechanism. psiM2 is a deletion derivative of the wild type psiM1 and lacks a 0.7-kbp deletion segment, which makes it more stable than the wild type. Both variants are virulent, encoding pseudomurein endoisopeptidase, an enzyme that cleaves host pseudomurein. However, a putative integrase gene is also found in psiM1 and psiM2. It has been observed that ~15% of psiM1 particles carry multimers of a cryptic 4.5-kbp host plasmid pME2001, suggesting that psiM1 can mediate general transduction. Indeed, the virus has been shown to transduce some host chromosomal markers. A defective prophage related to psiM1 and

psiM2, psiM100, can be found in the chromosome of *Methanothermobacter wolfeii*. Upon hydrogen limitation, *Methanothermobacter wolfeii* cultures spontaneously lyse, however, without producing VLPs, but the autolysate contains pseudomurein endoisopeptidase encoded by psiM100. psiM100 genome is ~28.8 kbp and is 70.8% identical to psiM2, except for the region of 2.8 kbp, which is apparently an insertion from a virus non-related to psiM1 or psiM2.

Two virulent viruses, phiF1 and phiF3, infecting *Methanobacterium thermoformicum* have been isolated from an anaerobic sludge reactor. phiF1 has an icosahedral head of ~70 nm in diameter and a non-flexible tail of ~160 nm in length, while phiF3 has an icosahedral head of ~55 nm in diameter and a flexible 230-nm long tail. The two viruses differ significantly in their host ranges, genome organization, and size. From the tested *Methanobacterium* strains, phiF1 infected *M. thermoautotrophicum* strain ΔH and several strains of *M. thermoformicum*, while phiF3 was able to infect only *M. thermoformicum* strain FF3. phiF1 has a linear dsDNA genome of ~85 kbp, while phiF3 genome is a circular or terminally redundant linear dsDNA molecule of ~36 kbp. No similarity between their sequences were found in hybridization experiments. There is no complete genome sequence available for these viruses. The other siphovirus infecting methanogenic euryarchaea, Drs3, (Table 1) is only distantly related to psiM2 or psiM100, having no predicted functions for the majority of ORFs.

Icosahedral Internal Membrane-Containing Viruses

Currently, five icosahedral internal membrane-containing viruses infecting euryarchaea have been described, SH1 being the first virus isolate of this group (found 2005; Table 2). Their genomes are either linear or circular dsDNA molecules. These viruses are classified into the family *Sphaerolipoviridae* together with the phages P23–77 and IN93 infecting thermophilic *Thermus* bacteria. *Alphasphaerolipovirus* genus includes virus species of *Haloarcula hispanica* viruses SH1, PH1, and HHIV-2, and *Haloarcula californiae* virus HCIV-1. *Natrinema* virus SNJ1 is the sole member of the genus *Betasphaerolipovirus*, and the bacteriophages have their own genus *Gammasphaerolipovirus*.

Archaeal sphaerolipoviruses have been isolated from different hypersaline environments: Australian salt lakes and solar salterns in Italy and Thailand (Table 2). Their host cells are either *Haloarcula* or *Natrinema* species. SH1, PH1, HHIV-2, and HCIV-1 are virulent and their progeny is released by host cell lysis. SNJ1 is temperate and initially found from lysogenic strain *Natrinema* sp. J7–1 originating from a salt mine, Hubei province, China. The strain J7–1 contains a plasmid pHH205, whose sequence is identical to that of SNJ1 and it is the proviral element of SNJ1 replicating freely in the cell. SNJ1 employs a rolling-circle mechanism of genome replication and harbors a gene encoding replication initiation protein. SNJ1 can be induced by mitomycin C and plated on *Natrinema* sp. J7–2 strain to obtain plaques. *Natrinema* sp. J7–1 is also the source of another halophilic virus SNJ2, which is a pleomorphic virus (Table 3).

Archaeal sphaerolipovirus virions are icosahedral, ~80 nm in diameter, and contain more than 12 different protein types, which are either forming the capsid, receptor recognizing spike complexes, or associating with the membrane. Underneath the icosahedral capsid, the protein-rich membrane bilayer encloses the genome. This virion morphology is also found among crenarchaeal (e.g., turritivirus STIV and STIV-2) and bacterial viruses (e.g., tectivirus PRD1 and corticovirus PM2). The recently obtained cryo-EM based whole virion structures of HCIV-1, HHIV-2, and SH1 at 3.7–3.8 Å resolution revealed that virus capsids are arranged in a pseudo $T = 28$ dextro lattice composed of two MCP species (Fig. 4). MCP VP7 is smaller and composed of one single β -barrel, whereas the large MCP VP4 is composed of two β -barrels. One β -barrel is forming the lattice and the other one is located on top of the lattice-forming β -barrel, thus forming the tower structure on the capsomer surfaces (Fig. 4(B)). The MCPs are conserved among the archaeal sphaerolipoviruses and the amino acid similarities of the large MCP VP4 and small MCP VP7 are 90%–97% and 86%–99%, respectively. MCPs VP4 and VP7 form pseudo-hexameric capsomers with either two or three towers, which are built of VP7-VP4 heterodimers and monomeric VP7. The capsid assembly is coordinated by the conserved penton protein complexes at the five-fold vertices and two specific membrane associated GPS-II and GPS-III complexes. The bacterial sphaerolipovirus P23–77 capsid has the same $T = 28$ organization, but the sequences of its MCPs are divergent from those of the archaeal counterparts although having similar single β -barrel folds.

The multi-protein spike complexes are either dimeric horn-shaped structures (SH1, HCIV-2, and PH1) or pentameric propeller-like complexes (HHIV-2) plugged into the five-fold vertices serving as host recognition devices. The viral membranes are composed of virus-encoded proteins and host-derived lipids, which are selectively acquired from the host membranes during the virion assembly. The membrane is closely associated with the capsid, being connected to the capsid at least by the penton and GPS-complexes. The major lipid species in HCIV-1, HHIV-2, and SH1 virions are phosphatidylglycerol, phosphatidylglycerophosphate methyl ester, and phosphatidylglycerosulfate. In a similar way, the fatty acids of SNJ1 are of the host origin, but the composition is a bit different than in viruses of *Haloarcula*.

The ~30 kbp genomes of HCIV-1, HHIV-2, SH1, and PH1 are linear and have inverted terminal repeats and terminal proteins attached to the ends of the molecules, proposing a protein-primed mechanism of genome replication. However, no canonical DNA polymerase-encoding gene such as in the genome of bacteriophage phi29 is found in viral or host genomes, indicating that a different mode of replication might be employed. The genomes of HCIV-1, HHIV-2, SH1, and PH1 share over 56% nucleotide identity. SH1 and PH1 are the most closely related viruses with ~76% identity. The four genomes are co-linear and the organization of their ~50 ORFs is conserved (Fig. 5).

The circular SNJ1 genome sequence shares little similarity to other archaeal sphaerolipoviruses at the nucleotide level. However, the arrangement of the viral core genes encoding putative genome packaging ATPase and the small and large MCPs is

Fig. 4 Cryo-EM structures of HCIV-1 and HHIV-2 virions and their MCPs. (A) Cryo-EM density maps of HCIV-1 (left) and HHIV-2 (right) (vertex complexes have been omitted). HCIV-1 is rendered to display the capsid shell (left-half) and the particle interior (right-half). Color-coding by distance from the center (legend below); genome, red; inner and outer membrane leaflets, yellow and yellow-lime. Icosahedral asymmetric unit (IAU) and capsomer organization are shown on HCIV-1 surface (white-transparent hexagons) and at the center. Capsomers are numbered Nos. 1–5; the three-tower capsomers (No. 1, light-yellow; No. 2, cyan; No. 3, pink) and two-tower capsomers (No. 4, light-green; No. 5, light-magenta). Two MCPs VP4 and VP7 are visualized by blue and light-gray circles. The MCP subunits are labeled (A–X and a). Black short-lines joining the circles identify the VP7–VP4 heterodimers. Black pentagons represents the positions of the penton complex plugging the vertices. Facet of the virion and the icosahedral symmetry axes (two, three, and five-fold) are marked on HHIV-2 by a white triangle and numbers (2, 3, and 5), respectively. (B) Single β -barrel MCPs VP7 (left) and VP4 (right) of HCIV-1. VP4 is composed of two vertical single β -barrels, one standing on top of the other, while VP7 consists of a vertical single β -barrel. The four-stranded sheets BIDG and CHEF are labeled in VP7. A loop in VP7 (residues 149–154) is marked by a dashed circle. Region of the VP4 atomic model is shown as a stereoview (black rectangles) and fitted into the corresponding 3.7 Å resolution density map. Reproduced from Santos-Pérez, I., Charro, D., Gil-Carton, D., *et al.*, 2019. Structural basis for assembly of vertical single β -barrel viruses. *Nature Communications* 10, 1184.

conserved. These three genes are the most conserved among HCIV-1, HHIV-2, SH1, and PH1, and can be also found from bacteriophages belonging to the same family. The least conserved genes are encoding the receptor recognition complexes. The HHIV-2 spike complex genes are different from those found in the same position of the genomes of HCIV-1, SH1, and PH1 (Fig. 5) as are the structures of their vertex complexes. Putative proviruses HalaCibP1, HalaPauP1, and HaloLacP1 identified in the chromosomes of *Haladaptus cibarius*, *Haladaptus paucihalophilus*, and *Halobiforma lacisalsi* resemble HCIV-1, HHIV-2, SH1, and PH1 viruses and have signatures of putative integrase or transposase and tRNA genes flanking the sphaerolipovirus-like provirus sequences, indicating that some of these viruses could be temperate alphasphaerolipoviruses. In addition, two euryarchaeal

Fig. 5 Genome comparison of icosahedral membrane-containing euryarchaeal dsDNA virus isolates belonging to the family *Sphaerolipoviridae*. Gray arrows, ORFs and genes; other colored arrows, homologous genes coding for structural virion proteins (VPs) indicated above; light blue arrow heads, inverted terminal repeats (ITR). The nomenclature for the virion proteins (VPs) is same in all four viruses except that the vertex complex proteins that are marked with asterisks: HHIV-2 proteins VP16 and VP17 and proteins VP3 and VP6 in other viruses. Genes encoding putative vertex complex proteins are bordered with black lines. Pairwise amino acid similarities (%) between the major membrane proteins (VP12), major capsid proteins (MCPs), or putative packaging ATPases are shown in between the genomes. Reproduced from Demina, T.A., Pietilä, M.K., Svirskaitė, J., *et al.*, 2017. HCIV-1 and other tailless icosahedral internal membrane-containing viruses of the family *Sphaerolipoviridae*. *Viruses* 9, 32.

proviruses TKV4 and MVV (putatively forming icosahedral particles) can be found integrated into the chromosomes of *Thermococcus kodakaraensis* KOD1 and *Methanococcus voltae* A3.

Pleomorphic, Spindle-Shaped, and Spherical Viruses

Pleomorphic, spindle-shaped, and spherical viruses of euryarchaea have non-lytic life cycles. From these groups, halophilic pleomorphic viruses are the most numerous with 18 virus isolates described today (Table 3). A few spindle-shaped (i.e., lemon-shaped) viruses have been isolated on halophilic or thermophilic euryarchaea, whereas the only example of a spherical euryarchaeal virus is MetSV of anaerobic methane-producer *Methanosarcina* (Table 3).

Pleomorphic Viruses

Since the discovery of the first archaeal pleomorphic virus HRPV-1 in 2009, altogether 18 pleomorphic viruses infecting halophilic euryarchaea have been described. Fifteen of those are members of the family *Pleolipoviridae*, which is the first virus family containing viruses with either ssDNA or dsDNA genomes (Table 3). In addition, three virus isolates are tentative species of the family. Here, we briefly summarize the current knowledge on the life cycles, virions, and genomic sequences of pleolipoviruses. For more information, please see the further reading “Vesicle-Like Archaeal Viruses”.

The majority of pleolipoviruses have been isolated on halophilic archaea belonging to the genera *Halorubrum* and *Haloarcula* of the class Halobacteria. Pleolipoviruses establish non-lytic infection, presumably using budding as an exit mechanism. Virus particles are produced continuously, and the host growth is typically retarded. SNJ2 is a temperate virus, and some other viruses harbor also integrase-encoding genes in their genomes. Pleolipoviruses lack a rigid protein capsid, instead, their virions are flexible membrane vesicles (Fig. 6). Virions have only 2–4 structural protein types, of which the spike induces the fusion of viral and host membranes during virus entry.

Pleolipoviruses have either ssDNA or dsDNA circular genomes, except His2, whose genome is a linear dsDNA molecule (Table 3). All pleolipovirus genomes carry a conserved block of collinear genes. Based on whole genome information and gene content, the pleolipoviruses are classified into *Alphapleolipovirus*, *Betapleolipovirus*, and *Gammapleolipovirus* genera. In addition, proviral sequences related to pleolipoviruses are commonly found in genomes of halophilic archaea, indicating that they are quite common in hypersaline environments.

Spindle-Shaped Viruses

Spindle-shaped viruses are so far found only in archaeal viruses. There are several crenarchaeal spindle-shaped viruses belonging to the family *Fuselloviridae*, but His1 is the only halophilic euryarchaeal spindle-shaped virus and it infects *Haloarcula hispanica*. His1 is taxonomically assigned into the genus *Salterprovirus* in the newly proposed family *Halspiviridae*. The linear dsDNA genome of His1 encodes a putative type-B DNA polymerase for protein-primed replication. The spindle-shaped His1 virion with a short tail is elastic and very stable in different conditions (Fig. 6). When inactivated (e.g., by treatment with non-ionic detergent or boiling), the spindle-shaped particle releases its genome and transforms into an empty tube. Similar mechanism might be used when the viral genome is injected upon host infection. His1 particles vary in size and are composed of only one MCP type and a few minor structural protein species. His1 MCP exists in two forms, one of which is modified with lipids. No lipid bilayer has been detected in His1 virion. Virion elasticity might be a consequence of the MCP lipid-modification. His1 life cycle is non-lytic and the infection leads to continuous virus production.

Fig. 6 Spindle-shaped virus His1 of the family *Halspiviridae*. (A) A slice through a tomogram of His1 viruses. (B–E) Structure of His1 virion is shown (B and C top and side views of the symmetry-free map; D and E top and side views of the sixfold symmetrized map). (F) The central slice of the refined sixfold average map showing the two cavities and a plug density. (G1–G3) Slices normal to the long axis of the virion at the indicated positions in F. Reproduced from Hong, C., Pietilä, M.K., Fu, C.J., *et al.*, 2015. Lemon-shaped haloarchaeal virus His1 with uniform tail but variable capsid structure. *Proceedings of the National Academy of Sciences of the United States of America* 112, 2449–2454.

TPV1 is the only described spindle-shaped virus isolate of hyperthermophilic euryarchaeon (**Table 3**). Its circular dsDNA genome can be found freely in high copy numbers in the host cell *Thermococcus prieurii*, from which it is produced continuously in a non-lytic fashion. VLP PAV1 is also spindle-shaped with a short tail but isolated from hyperthermophilic euryarchaeon *Pyrococcus abyssi*, from which it is continuously released (**Table 3**). However, its infectivity has not been demonstrated. PAV1 circular genome exists also as an episome in the *Pyrococcus abyssi* cytoplasm. Half of the PAV1 genome is composed of genes that have homologs in pTN2-like plasmids of *Thermococcus* strains. PAV1 persists most probably in its host in a stable carrier state. In addition, a spindle-shaped A3-VLP has been observed in a methanogenic euryarchaeon *Methanococcus voltae*. The major capsid proteins of the spindle-shaped viruses with a short tail His1 (type virus of *Halspiviridae*), PAV1, TPV1, A3-VLP, and SSV1 (type virus of *Fuselloviridae*) are homologous based on their sequence similarity, suggesting their close evolutionary relationship.

Spherical Virus Metsv

The only euryarchaeal virus with spherical morphology is MetSV, which has been isolated from an anaerobic sewage sludge on *Methanosarcina mazei* Gö1 (**Fig. 1(G)**, **Table 3**). Spherical particles are of ~57 nm in diameter and contain a blackberry-like envelope. Albeit having smaller size and no helical nucleoparticles, MetSV particles generally resemble PSV, the previously reported spherical virus infecting thermophilic crenarchaea of the genera *Pyrobaculum* or *Thermoproteus*. The analysis of viral and host lipids has revealed that virus particles contain an internal membrane composed of lipids obtained from the host. The presence of direct terminal repeats at the ends of the linear genome and a gene encoding a type B DNA polymerase suggest that MetSV is replicated via a protein-primed mechanism. The majority of MetSV ORFs could not be assigned with putative functions. MetSV is virulent, and its host range includes a few *Methanosarcina mazei* strains and *M. barkeri* strain DSM 1311 growing as single cells. However, sarcina-like aggregates are resistant to MetSV infection. MetSV-derived spacers have been identified (with

some mismatches) in Clustered Regularly-Interspaced Short Palindromic Repeats (CRISPR) loci in several *Methanosarcina* sp. genomes, but not in the type strain *M. mazei* DSM 3647.

Culture-Independent Studies

Microscopic examinations of hypersaline environments have revealed high VLP concentrations, typically up to 10^9 VLP/mL, and varying VLP/cell ratios (1 – 100). A variety of VLP shapes was observed in hypersaline environments with spindle-shaped VLPs being the most abundant ones, especially in the saltiest waters. Other observed morphotypes include spherical, filamentous, tailed icosahedral and some more unusual shapes. For example, star-shaped VLPs have been detected in the Dead Sea and a lot of unusual particle morphologies in hypersaline Lake Retba, e.g., hairpin-shaped and bacilliform particles, branched filaments, chains of small globules and others. It has to be yet noted that in microscopy, it is impossible to distinguish between bacterial and archaeal viruses, and e.g., pleomorphic VLPs can be confused with membrane vesicles commonly produced by cells.

Square archaeon *Haloquadratum walsbyi* is very abundant in hypersaline environments, but no viruses have been yet isolated for it. However, EM examination of environmental samples has revealed icosahedral tailed and spindle-shaped VLPs associated with square cells of *Haloquadratum* sp. In addition, pulse-field gel electrophoresis of environmental DNA from Santa Pola solar salterns, Alicante, Spain, with subsequent fosmid and plasmid clones construction and sequencing allowed a reconstruction of a near-complete genome sequence of EHP-1 (environmental halophage 1) presumably infecting *Hqt. walsbyi*. Among the other 42 partial viral genome sequences obtained from the same salterns, half could be tentatively assigned to *Hqt. walsbyi*, *Nanohaloarchaea*, or *Hrr. lacusprofundi*, indicating potential virus-host pairs. In addition, single-cell genomics and microarrays have been used for the identification of virus-host pairs in environmental samples of Santa Pola salterns, with NHV-1 (nanohaloarchaeal virus 1) and its nanohaloarchaeal host as the case study.

Metagenomic and metaproteomic analyses of the Deep Lake in Antarctica revealed that the lake is dominated by haloarchaea. Identified viral MCP sequences matched several haloarchaeal virus isolates: HCTV-1, HVTV-1, HCTV-2, HHTV-1, and CGphi46. The matches to HCTV-1-like prohead protease and HRTV-7-like scaffold protein sequences indicate active virus life cycles in the sampled community. The analysis of Antarctic salt lakes metagenomes has also revealed matches between archaeal CRISPR spacers and tailed halovirus isolates ChaoS9, phiH1, and phiCh1.

Virus-host interactions in hypersaline environments still remain largely unresolved. It has been shown that salt concentration changes, which are inevitable in natural environments, may affect adsorption rates, infectivity, and life cycle of haloarchaeal viruses. Virus-host systems in hypersaline environments seem to be diverse and dynamic. Generally, common features are found in meta-viromes from distant hypersaline environments, but finer-level spatial and temporal analyses often suggest controversial trends in viral dynamics. When compared to sequence databases, metagenomic datasets from hypersaline environments usually have a very limited number of hits. Virus defense systems such as CRISPR-Cas, commonly found in archaea, suggest a constant active interplay between viruses and their hosts.

Euryarchaeal viruses have been detected even deep in the ocean basement by metagenomics. A complete genome sequence (JdFR1000234; 55,906 bp) of a putative archaeal virus obtained from geothermally heated fluid samples collected from the ocean basement (117–292 m depth) of the Juan de Fuca Ridge, North America, encodes putative viral MCP, portal protein, and terminase, displaying similarities to archaeal icosahedral viruses with a long contractile tail. In addition, the complete viral genome of ANM-1, which presumably infects an anaerobic methane-oxidizing archaeon, was assembled from subsurface sediments collected from a methane seep (820 m depth) in Santa Monica Basin. ANM-1-related metagenomic sequences found from other methane seeps suggest that these viruses have a wide distribution in such environments. Interestingly, ANM-1 sequence contains diversity-generating retroelements, which together with similar elements found in the genomes of subterranean nanoarchaea represent the first examples of this genetic diversification-driving mechanism in archaeal systems. A variety of VLPs resembling archaeal viruses have been found in deep anoxic sediments of the Lake Pavin, France. Pleomorphic ellipsoid VLPs have been observed associated with filamentous cells, presumably belonging to methanogenic archaea of the genus *Methanosaeta*.

Recently, tens of genomes of viruses putatively infecting marine unculturable euryarchaea of Group II have been assembled from environmental viromes (the Red sea, Tara Oceans, and Osaka Bay viromes). These viruses, called magroviruses, possess dsDNA genomes of up to ~100 kbp, displaying similarities to euryarchaeal tailed viruses. Interestingly, magrovirus genomes appear to encode an extensive set of proteins involved in DNA replication, i.e., a nearly complete replication apparatus of the archaeal type. Marine euryarchaea and magroviruses seem to be globally widespread and abundant, although no such virus-host systems have been yet isolated.

Conclusions

The diversity of euryarchaeal viruses is still undersampled compared to that of viruses infecting bacteria or eukaryotes, limiting our understanding on their evolution and environmental impacts. The existing knowledge suggests that euryarchaeal viruses represent a very diverse group of viruses with various morphologies and life strategies. With detailed molecular studies, unexpected evolutionary links have been revealed between archaeal, bacterial or eukaryotic viruses, while environmental studies have shown that euryarchaea and their viruses are abundant and ecologically relevant in various environments, both moderate and extreme.

Possible evolutionary relations have been also suggested for membrane-enclosed pleomorphic viruses and membrane vesicles, commonly produced by cells. Much more research is needed to understand the relations within and beyond the group of euryarchaeal viruses, their interactions with host cells and the extent of their ecological roles.

Glossary

Alphapleolipovirus Pleolipoviruses with circular ssDNA genomes encoding putative rolling circle replication initiation proteins.

Archaeal virus Virus infecting organisms in the third domain of life, the *Archaea*.

Betapleolipovirus Pleolipoviruses with circular dsDNA genomes with short single stranded discontinuities.

Gammapleolipovirus Pleolipoviruses with linear dsDNA genomes with inverted terminal repeat sequences and a gene for putative type B DNA polymerase.

Glycosylation Addition of carbohydrate(s), i.e., glycan to another molecule. In this article, glycosylation is limited to proteins as target molecules.

Haloarchaea Extremophilic archaea that require NaCl concentration above 1.5 M for survival.

Integrase An enzyme that catalyzes the integration of viral genomic DNA into the genome of the host cell.

N-Glycosylation A mode of glycosylation where an asparagine (Asn/N) of a protein is modified with an addition of a glycan.

PhiH repressor Repressor protein whose gene was originally identified in the archaeal virus PhiH of

Halobacterium salinarum, with a function to repress the production of an early lytic transcript. PhiH-like repressor genes have been identified in the genomes of those pleolipoviruses that contain a putative integrase gene.

Pleolipovirus Archaeal virus with a vesicle-like virion architecture.

Receptor A molecule, usually exposed on the surface of the host cell, that the virus uses to recognize the host cell.

S-Layer protein (archaeal) Archaeal cell wall glycoproteins, which can self-assemble into a paracrystalline surface layer. S-layer proteins are candidates of pleolipovirus receptors.

Spike Structural virion surface protein, which usually protrudes from the surface of the viral particle and serves as the receptor recognition protein. In pleolipoviruses it also serves as a membrane fusion protein.

VP3-Like protein Pleolipovirus virion membrane associated protein, which resides for the most part, inside the virion. It is a homolog of HRPV-1 VP3 protein.

VP4-Like protein Pleolipovirus virion spike protein, which serves as the receptor recognition protein and fusion protein. It is a homolog of HRPV-1 VP4 protein.

Introduction

Haloarchaeal pleomorphic viruses (HRPVs) belong to a newly established family of *Pleolipoviridae*. The first isolate and now the typical member of the family, *Halorubrum* pleomorphic virus 1 (HRPV-1), was reported in 2009. It was also the first archaeal virus containing a single-stranded DNA (ssDNA) genome. Ever since, new representatives have been reported adding up to almost 20 different isolates that, after tailed viruses, represent the second largest group of viruses infecting haloarchaea (Table 1). Apart from representing the first archaeal viruses containing ssDNA genomes, the family *Pleolipoviridae* is also the first family, officially

Table 1 Reported Haloarchaeal pleomorphic viruses

classified by the International Committee on Taxonomy of Viruses (ICTV), which contains viral species harboring either single stranded or double stranded DNA (dsDNA) genomes. Despite the increasing number of new isolates and their genomic descriptions, we still have very little information about the detailed mechanisms of different steps in the viral life cycle. An exception to this is the recent report on the atomic structure of the HRPV spike protein, a membrane fusion protein, and its low-resolution structure on the virion (see *Structural proteins*).

Since viruses are obligate parasites, information on their host organisms is also crucial for understanding the interaction. One of the particularly important host factors for viral infections is receptors. According to the current understanding, the cell wall of most of the haloarchaeal strains consists of the cytoplasmic membrane (CM) covered by S-layer proteins that form a para-crystalline layer on the cell surface and a pseudo-periplasmic space between the CM and the surface of the S-layer. Not only S-layer proteins can be highly variable and thus represent the most probable candidate for the receptor, but they are also glycosylated. The haloarchaeal S-layer proteins are N-glycosylated, and as the types of glycosylation in different haloarchaeal hosts can be highly diverse, the glycan structures are also good candidates as receptors or as parts of them.

An Overview of the Virion Structure and Viral Life Cycle

The basic structure of the HRPV virions is a simple membrane vesicle enclosing the naked genome. A typical virion consists of two major structural proteins both of which are associated with the viral membrane. The larger structural protein, VP4 and VP4-like proteins (approx. from 50 to 60 kDa), forms spike structures on the surface of the virion whereas the smaller protein, VP3 or VP3-like proteins (approx. from 9–15 kDa), localizes mostly to the inner surface of the viral membrane (**Fig. 1**) without significant interactions with the genome.

The host range of the known HRPVs seems to be very narrow with only few, if any, additional strains identified in addition to the original isolation host. The life cycle of the pleomorphic viruses starts with the recognition of the host cell receptor by the spike proteins and the release of viral genome into the host cell cytoplasm in a membrane fusion event. Genome replication and transcription take place in the cytoplasm, most probably using at least two different mechanisms (see Family *Pleolipoviridae*: related viruses with different genome types) and the structural proteins together with the replicated genomes are translocated to the cytoplasmic membrane for assembly into the virions. Exit of virions occurs by budding. In that process, virions acquire their membrane from the host CM. Thus, lipid composition of the viral membrane is approximately the same as the one of the host CM. Infected cells produce new progeny viruses for several hours after the first new virions are detected.

The infection cycle for most of the characterized viruses is persistent, but detailed dynamics of different HRPV life cycles can vary substantially. For instance, HRPV-1 infects only approximately 10% of the host population at the start of the infection whereas HRPV-6 is able to infect at least 80% of the cells within the first 30 min. The duration of a life cycle of different HRPVs are relatively fast varying between approximately 2–5 h. Production of viruses by the cells retards the growth of the culture and leads in some instances to an inability to form colonies on rich culture media. The first reported temperate pleolipovirus, SNJ2, is able to integrate into the tRNA^{Met} gene of the host, *Natrinema* sp. J7–1. Interestingly, SNJ2 seems to have some type of a synergistic relationship with an icosahedral virus, SNJ1, as the presence of SNJ1 increases the titer of SNJ2 during co-infection.

Fig. 1 Schematic representation of pleolipovirus virion structure. Spike proteins are indicated with purple color, internal membrane proteins with turquoise, lipid bilayer with orange and DNA with black and DNA-binding terminal proteins in light green.

Genomic Characteristics

Gene Content and Conserved Genes

The genomes of the first reported HRPVs, *Halorubrum* pleomorphic virus 1 (HRPV-1) and *Haloarcula hispanica* pleomorphic virus 1 (HHPV-1), were circular molecules containing less than 10 predicted open reading frames (ORFs). The identity of the genes encoding the two major structural proteins, VP3 (14 kDa) and VP4 (53 kDa), was verified using N-terminal sequencing. In addition, thorough mass spectrometry analysis of HRPV-1 particles revealed one peptide belonging to gene 8 encoding a putative nucleoside-triphosphatase (NTPase) and possibly being crucial to the particle formation. Comparative genomics, using the two HRPVs mentioned above as well as previously reported haloarchaeal plasmid pHK2, revealed a conserved cluster of the two major structural protein encoding genes as well as ORFs 2, 5 and 6. In addition, all these genetic elements contained an ORF encoding putative rolling circle replication (RCR) protein that was not necessarily conserved in sequence, but in the predicted function.

As new isolates of pleomorphic viruses, *Halorubrum* pleomorphic viruses 2 and 6 (HRPV-2 and HRPV-6) and especially *Halorubrum* pleomorphic virus 3 (HRPV-3) and *Haloarcula hispanica* pleomorphic virus 1 (HHPV-1) were reported, the number of conserved genes and predicted, conserved ORFs was reduced to five. Thus, in the HRPV-1 genome, the conserved gene cluster starts from the most conserved (in sequence) gene 3 and ends after the putative dNTPase encoded by gene 8 (Fig. 2(a)). The conserved genes of HRPV-3 and HGPV-1 show lower sequence similarity with the ones of the other viruses, and they do not contain a homolog of the RCR, but a conserved gene containing predicted winged helix-turn-helix (wHTH) domain. The gene content outside the conserved gene region also varies from genome to genome.

His2 was the seventh virus originally included in the proposal for a new family of viruses, the *Pleolipoviridae*. It was isolated by the laboratory of Mike Dyll-Smith from an Australian salt lake on a lawn of *Haloarcula hispanica*. Unlike all the other genomes characterized to date, the genome of His2 was shown to be a linear dsDNA molecule with yet another suggested replication mechanism, the so-called protein primed replication with proteins covalently attached to the 5' ends of the genome. The genome of His2 is the most divergent from the other pleomorphic virus genomes in that it contains two clearly different parts, one of which contains the gene region conserved in the pleomorphic viruses. The conserved gene region of His2 genome resembles the most those of HRPV-3 and HGPV-1.

Family Pleolipoviridae: Related Viruses With Different Genome Types

The initial proposal of the new family *Pleolipoviridae* included eight viral isolates HRPV-1 (the typical member), HRPV-2, HRPV-3, HRPV-6, HHPV-1, HHPV-2, HGPV-1 and His2 (Fig. 2(a)). As outlined above, they all contain the conserved genomic region encoding the HRPV-1 VP3 and VP4 homologs, the two major structural proteins of the virion. In the other viral isolates, these proteins can be encoded by genes assigned with a different number, which depend on the genomic content. For example, the bigger major structural protein of HRPV-2 is encoded by gene 5. In that case, the protein is VP5 and it is a VP4-like protein.

Fig. 2 Genomic comparison of pleolipovirus genomes. (a) Different representative viruses of the Pleolipoviridae family. (b) Betapleolipoviruses. Reproduced from Bamford, D.H., Pietilä, M.K., Roine, E., *et al.*, 2017. ICTV virus taxonomy profile: *Pleolipoviridae*. Journal of General Virology 98, 2916–2917. doi:[10.1099/jgv.0.000972](https://doi.org/10.1099/jgv.0.000972) (under the licence CC BY 4.0, <https://creativecommons.org/licenses/by/4.0/>). Atanasova, N.S., Demina, T.A., Krishnam Rajan Shanthi, S.N.V., Oksanen, H.M., and Bamford, D.H., 2018b. Extremely halophilic pleomorphic archaeal virus HRPV9 extends the diversity of pleolipoviruses with integrases. Research in Microbiology 169, 500–504. doi:[10.1016/j.resmic.2018.04.004](https://doi.org/10.1016/j.resmic.2018.04.004) (under the licence CC BY, <https://creativecommons.org/licenses/by/4.0/>).

Downstream from the genes encoding the two major structural proteins, there are two conserved open reading frames encoding proteins with as yet unassigned functions, as well as the putative NTPase. The assignment of the viral isolates into different genera i.e., *Alpha*-, *Beta*- and *Gammapleolipovirus* is based on the gene content outside the conserved gene region. HHPV-1, HHPV-2, HRPV-1, HRPV-2 and HRPV-6 isolates, which carry the ORF encoding the putative RCR, are included in the *Alphapleolipovirus* genus. The assignment of HRPV-3 and HGPV-1 to the *Betapleolipovirus* genus is due to the presence of conserved hypothetical gene containing the wHTH domain. As mentioned above, the genome of His2 is different in terms of the other gene content and is assigned to the genus *Gammapleolipovirus*.

It is notable that despite of the relatedness of these viral isolates their genome type can be different. In general, the genomes of *Alphapleolipoviridae* members contain ssDNA genomes whereas the genomes of *Betapleolipoviridae* isolates contain dsDNA genomes. An intriguing feature of the genomes belonging to the latter genus is that the otherwise dsDNA genomes contain short genomic regions of ssDNA. In HRPV-3, where these discontinuities were reported for the first time, the ssDNA regions were found to be associated with a specific penta-nucleotide motif GCCCA (5' → 3') which precedes the ssDNA region of the same strand. Later on, similar discontinuous genomes have been reported for pleolipoviruses HHPV3, HHPV4 and HRPV9. Although the biological meaning of these short stretches is unknown, it has been hypothesized that, upon infection, that they would have a role in attracting the host DNA repair system components for active replication. Thus, despite the lack of information on the detailed mechanisms of genome replication, it is evident that these mechanisms are different for isolates belonging to the different genera.

New Isolates and Haloarchaeal Genomic Regions

Analyzes of the HRPV genomes showed that homologs of the *Alphapleolipovirus* genomes were present in previously reported, partially sequenced plasmid pHK2 of *Haloferax* sp. Sequencing of the entire 10.8 kb pHK2-plasmid showed that this virus-related genetic element, in addition to the conserved genomic region similar to the pleolipovirus genome, also contains an open reading frame encoding a putative integrase as well as a putative homolog of the phiH repressor gene. A homologous 12.5 kb genomic region in *Haloferax volcanii* genome spanning from a tRNA^{Arg} gene close to HVO_1434 all the way to HVO_1422 was also identified suggesting that the smaller viral genomes originated from bigger genomes of temperate viruses with a typical propensity to integrate into genomic tRNA genes. In fact, in haloarchaeal genomes there seems to be a wealth of integrated proviruses or proviral remnants related to pleolipoviruses, and especially to the viruses belonging to the *Betapleolipovirus* genus. Indeed, in 2014, a pleolipovirus genome, SNJ2, of the betapleolipovirus type was, for the first time, reported to contain both the integrase and the phiH repressor encoding genes. Also, HHPV4 and HRPV9 genomes have recently been shown to harbor both the integrase and the phiH repressor (Fig. 2(b)), and homologs of the SNJ2-type of integrases have been identified in numerous mobile genetic elements found in haloarchaeal genomes.

Stability of Pleolipovirus Infectivity

Salinity

Haloarchaeal organisms thrive in hypersaline conditions with, for instance, saturated NaCl concentrations (approximately 5.5 M). Thus, the most important environmental condition affecting the infectivity of pleolipoviruses is the high NaCl concentration. Most pleolipoviruses lose infectivity at NaCl concentrations below 1 M. Different pleolipoviruses vary slightly in their NaCl requirements. HRPV-1 is stable in a narrow range of 1–3 M NaCl, while betapleolipoviruses HRPV-3, HRPV-9, and HGPV-1 were found to be stable in NaCl concentrations varying between 0 M to above 5 M (saturation), during the 24 h incubation time, while HHPV3 and HHPV4, require at least 2.5 M NaCl. A peculiar and apparently pH-dependent infectivity at changing NaCl concentration was observed for pleolipoviruses HHPV3 and HHPV4. HHPV3 was able to maintain the infectivity at pH values 4.5–9 when NaCl concentration was 3.5 M. However, when NaCl was lowered to 1.5 M, the virus lost all infectivity at the optimum pH 7.5. At pH 9, on the other hand, the infectivity was maintained high even at 1.5 M NaCl. Similar pH-dependence was observed for HHPV4, which, genetically, is almost identical to HHPV3. The loss of infectivity was irreversible for both viruses. When HHPV-1 adsorption was studied at different salinities, maximum adsorption was detected when NaCl molarity was as high as 3.5 M. In addition to NaCl, pleolipoviruses HHPV3 and HHPV4 require at least 4 mM CaCl₂ concentration for stability and small amounts of CaCl₂ are used standardly for the other viruses as well.

Temperature and Other Significant Factors

Virus stock preparations of all pleolipoviruses are stable for months when stored at 4°C. The natural environments of halophilic archaea are mostly located in tropical or subtropical areas and exposed to intense sunlight. Thus, it is logical that their viruses require temperatures above 30°C for optimal infection. The most commonly used temperature for studying pleolipoviruses is 37°C. Incubation of the virions at temperatures higher than 40°C abolishes infection. Recently, it was shown that in the case of the spike proteins of HRPV-6, heat treatment at 55°C induces a drastic conformational change leading to an extended conformation of the spike proteins (see also: Structural proteins).

In general, pleolipovirus infectivity is lost in detergents and organic solvents as well as negative stains used in transmission electron microscopy. Some viruses, such as HRPV-6, HRPV-8, HRPV9, and HRPV10 stand out as being more resistant to chloroform (in the test conditions used) than other pleolipoviruses. The reasons for this stability of a lipid-membrane containing particle to chloroform are not known. The effect of negative stains on the pleolipovirus infectivity has been studied to answer the question whether the virion morphology observed in the ordinary negatively stained samples represent the one of infective virions. Most of the negative stains abolish the infectivity, but no clear correlation with the virion morphology has been found. Thus, ordinary negative stain transmission microscopy cannot be used for determining the morphology of an infectious pleolipovirus particle.

Structural Proteins

As mentioned above, the basic pleolipovirus virion contains two major structural proteins, both of which are associated with the membrane envelope of the virion. In addition, traces of the conserved ORF encoding the putative NTPase can be found. However, some of the isolates belonging to the *Beta*- and *Gammapleolipovirus* genera, seem to contain some additional structural proteins. For instance, in His2 virions there are two protein species making the spikes as well as two protein species serving the role of the smaller membrane protein. Quantitative biochemical dissociation studies for the smaller membrane protein have shown that it is membrane associated and mostly exposed to the lumen of the virion. However, it does not seem to have strong interaction with the genome.

The Spike Protein

The spike protein has been studied more intensively due to its role in host recognition and membrane fusion. All the spike proteins contain an N-terminal signal peptide for either Sec- or predicted Tat-secretion pathway. They also contain a C-terminal trans-membrane domain (TM) with which the spike protein stays anchored to the viral membrane. This has been shown experimentally for HRPV-1 and HRPV-6 virions. The primary amino acid sequence for the different spike proteins can be highly variable, which is common for the viral proteins involved in host recognition. Thus, as such it cannot be considered to be among the conserved proteins of the virus. However, its position as one of the conserved proteins is warranted as in all viruses it seems to serve the same function as a spike protein, and its position in the genomic context of the gene is always the same.

Different types of modifications bring additional variation to the spike protein properties. The HRPV-1 spike protein is N-glycosylated with a pentasaccharide that comprises glucose, glucuronic acid, mannose, sulphated glucuronic acid and 5-N-formyl-legionaminic acid residue as the terminal sugar. There is also evidence suggesting that this glycan structure is involved in the recognition of the host receptor. This post-translational modification must take place in the pseudo-periplasmic space as described for the S-layer proteins of haloarchaea. None of the spike proteins from other pleolipovirus species have been shown to be glycan modified. However, such a role of glycans in specific receptor recognition may also be true for other pleolipoviruses, but provided by glycan modifications of the host S-layer. As there are no genes predicted to be involved in N-glycosylation pathways in the pleolipoviral genomes, the glycosylation is dependent on the host glycosylation machinery. This was shown by heterologous expression of the HRPV-1 VP4 in *Hfx. volcanii* in which case the N-glycan structure was the same as described for *Hfx. volcanii* S-layer protein N-glycan. In addition to the reported glycan modification, one of the two spike proteins of His2 virus was predicted to contain lipid modifications since the protein was positively stained with Sudan Black. The possible biological function of this modification is not known.

Fig. 3 Structure of the HRPV-6 spike and the spike protein VP5. (a) Cartoon representation of the spike protein colored from the N-terminal (blue) to the C-terminal (red). (b) Density of the spike on virion surface as solved by cryo-electron tomography and subtomogram averaging with HRPV-6 VP5 crystallographic structure fitted into the density. Reproduced from El Omari, K., Li, S., Kotecha, A., *et al.*, 2019. The structure of a prokaryotic viral envelope protein expands the landscape of membrane fusion proteins. *Nature Communications* 10, 846, doi:10.1038/s41467-019-08728-7, under the licence CC BY 4.0, <http://creativecommons.org/licenses/by/4.0/>.

The atomic structure of the HRPV-2 and HRPV-6 spike proteins (VP4-like protein VP5) has been determined at 2.5 and 2.7 Å resolution, respectively. Both proteins, approximately 65% identical in their primary amino acid sequence, show highly similar structures. The overall protein structure is a previously unreported V-shaped fold dividing the protein in two major domains that are connected with a single residue (Fig. 3). The lowest similarity, both in amino acid sequence and in structure, was shown to be in a domain that, when fitted to a 16 Å resolution cryo-EM structure of the spike on the HRPV-6 virion, was pointing outwards from the spike structure. Thus, this domain was suggested to be involved in host recognition.

In addition to the host recognition, these spike proteins were also shown to be involved in fusion of the viral membrane with the host cell membrane. The highly alpha-helical secondary structure of the N-terminal domain was predicted to be involved in this process. It was hypothesized that upon the interaction of the putative host recognition domain with the host S-layer protein, the N-terminal alpha helical structure will open with concomitant exposure of the fusion peptide at the very N-terminus of the protein to the host membrane.

Nomenclature

Acr Anti-CRISPR

cOAs Cyclic oligoadenylates

ESCRT Endosomal sorting complex required for transport

MCP Major capsid protein

ORF Open reading frame

S-layer Surface layer

T4P Type 4 pilus

TA Toxin-antitoxin

Glossary

Adsorption rate Rate at which extracellular virions become attached to the host.

A-form One of the three major forms of double-stranded DNA, with a 23 Å helical diameter and 11 bp per helix turn.

Capsid Protein shell that encloses the genetic material of the virus.

Episomal element Extrachromosomal (non-integrated) form of a mobile genetic element inside the host cell.

Holliday junction resolvase A specialized structure-selective endonuclease that cleaves four-way DNA intermediates formed during DNA replication.

Homologous recombination Recombination between two identical or highly similar DNA sequences.

Hyperhalophiles Organisms thriving in the presence of extremely high salt concentrations.

Hyperthermophiles Organisms requiring extremely high (80°C or above) temperatures for optimal growth.

Integrase Enzyme that catalyzes the integration of a viral genome into the genome of the host cell.

Inverted terminal repeats Short, related or identical sequences located in reverse orientation at the ends of the viral genome.

Jelly-roll fold A structural protein fold composed of eight β-strands arranged in two antiparallel four stranded β-sheets.

Lysogenic life cycle One of the two alternative life cycles of a virus, whereby the virus genome integrates into the host chromosome as a provirus or remains as a dormant episomal element.

Lytic life cycle One of the two alternative life cycles of a virus, whereby the virus replicates inside the host and lyses the infected cell releasing the progeny viruses to infect other cells.

Methanogenic Producing methane as a metabolic by-product in anoxic conditions.

Orthologous genes Homologous genes that are related by vertical descent from a common ancestor and encode proteins with the same functions in different species.

Phase variation system Reversible process that involves the ON/OFF switching of protein expression to adapt to rapidly changing environments generating phenotypical variations within the population.

Protein glycosylation Post-translational modification where a carbohydrate molecule is covalently bound to a predetermined region of a protein to form a glycoprotein.

Provirus Viral genome integrated into the host chromosome.

Pseudomurein endoisopeptidase An enzyme that cleaves pseudomurein cell-wall sacculi of methanogens.

Rolling-circle replication Model of unidirectional DNA replication that can rapidly synthesize multiple copies of circular ssDNA molecules.

S-layer A paracrystalline protein surface layer that is present in nearly all archaea described so far.

Strand-coupled genome replication Model of DNA replication that couples leading-strand and lagging-strand synthesis.

Strand-displacement Displacement of a downstream DNA strand encountered during DNA replication.

Type 4 pili Surface-exposed filaments involved in many functions of the cell, including locomotion, adhesion, microcolony formation and protein secretion.

Virion Infectious mature virus particle.

Introduction

Viruses infecting archaea constitute a distinctive part of the virosphere and exhibit diverse virion morphologies, many of which have never been observed among viruses infecting bacteria or eukaryotes. Diversity of archaeal viruses is also reflected in their genome content, with ~75% of the genes lacking detectable homologs in sequence databases. Based on their diverse virion morphologies and genomic properties, the characterized archaeal viruses are currently classified into 20 families. Although the knowledge of virus-host interactions in archaea remain highly fragmented, the increasing number of genetic tools developed for archaea and their viruses as well as application of advanced structural and functional genomics efforts have yielded valuable information on certain aspects of virus-host interactions. Some of these mechanisms are shared with bacterial and/or eukaryotic viruses, whereas others are unique to archaeal viruses.

The virus infection cycle can be subdivided into several stages. The infection starts with the recognition and binding to specific host receptors on the host cell surface which leads to the delivery of the viral genetic material into the cell interior. Following the entry, many viruses hijack the host replication, transcription, and translation machineries to produce multiple copies of the virus progeny. For some enveloped viruses, the morphogenesis and egress are concomitant, whereas in the case of non-enveloped viruses the virion assembly typically precedes the release. Thus far, two different egress strategies have been elucidated for archaeal viruses: a budding mechanism similar to that of some eukaryotic enveloped viruses and a unique lytic mechanism employed by certain crenarchaeal viruses which involves the formation of pyramidal structures on the host cell surface. Similar to bacteriophages and certain eukaryotic viruses, some archaeal viruses can undergo lysogenic life cycle, whereby the virus genome integrates into the host chromosome as a provirus or remains as an episomal element until the cell host is exposed to certain stimuli or stress conditions that induce viral replication. Archaea and their viruses have evolved diverse defense and counter-defense mechanisms, among which CRISPR-Cas system and anti-CRISPR (Acr) proteins have been the most studied.

In this article, we review the state-of-the-art on virus-host interactions in Archaea. Note that most studies have focused on just a handful of model virus-host systems, including *Sulfolobus islandicus* rod-shaped virus 2 (SIRV2; family *Rudiviridae*), *Sulfolobus* spindle-shaped virus 1 (SSV1; family *Fuselloviridae*), *Sulfolobus* turreted icosahedral virus (STIV; family *Turriviridae*) and *Sulfolobus tengchongensis* spindle-shaped virus 2 (STSV2; family *Bicaudaviridae*), all infecting hyperthermophilic archaea of the genus *Sulfolobus* (phylum Crenarchaeota).

Virus Entry

The infection cycle begins with the recognition of a suitable host through specific interactions between a receptor-binding protein exposed on the virion and a receptor located on the surface of the host cell. Once the viral protein successfully binds to the host receptor, the virus particle typically undergoes a conformational change that results in the delivery of the genetic material into the cytoplasm of the host cell. For the well-studied viruses infecting bacteria, different cell surface structures have been recognized to be targeted by viruses including pili, flagella, peptidoglycan, lipopolysaccharide and integral membrane proteins. Viral attachment and entry have been poorly studied in archaea and only recent efforts have provided the first insights into the entry mechanisms and possible receptors of hyperthermophilic and hyperhalophilic archaeal viruses.

Interaction With Cellular Appendages

Similar to bacteria, archaea possess distinct cell surface appendages, including archaeal flagella (archaella) implicated in cell motility and diverse pili involved in intercellular communication and adhesion to various organic and inorganic substrates. Electron microscopy observations showed that many filamentous viruses bind to pili. For instance, termini of the filamentous virions of members of the *Lipothrixviridae* family are decorated with diverse structures, which resemble claws (AFV1), brushes (AFV2) or mops (SIFV), and have been proposed to play a role in the viral attachment to the host cell, specifically to pilus-like appendages.

The interaction of SIRV2, the prototype virus of the family *Rudiviridae*, with cellular appendages has been studied in more detail. Both ends of the rod-shaped SIRV2 virions contain three terminal fibers which specifically interact with the pili abundantly present on the surface of *Sulfolobus islandicus* LAL14/1 cells. Notably, when the pili were detached from the cells, the virus interacted nearly exclusively with the tips of the pili, whereas in the context of metabolizing cells, the virions were observed both at the tips and on the sides of the pili, suggesting that virions move along the pili toward the cell surface. However, the energy source for this movement remains unclear. Once at the cell surface, the SIRV2 virions appear to disassemble, presumably as a consequence of the delivery of the viral DNA into the host cytoplasm. Similarly, rudivirus SSRV1 and tristromavirus PFV2 have also been shown to interact with the type IV pili (T4P) of *Saccharolobus solfataricus* and *Pyrobaculum arsenaticum*, respectively (Fig. 1(A)–(D)). Deletion of the orthologous pilin genes, *pilA1* and *pilA2*, in *S. islandicus* M.16.4 resulted in loss of T4P and resistance to rudivirus SIRV8, a close relative of SIRV2, which could no longer adsorb to the host cell. These observations further reinforce the critical role of pili during the early stages of archaeal virus infection.

A near-atomic structure of the SIRV2 receptor showed that it is a T4P. Remarkably, the pilus was extremely stable and resisted various harsh treatments, including digestion by trypsin and pepsin as well as boiling in sodium dodecyl sulfate and 5 M guanidinium-HCl. The resilience of the pilus was attributed to extensive surface glycosylation on serine and threonine residues, which are anomalously abundant in the *Sulfolobus* T4P, compared to the bacterial T4P and other *Sulfolobus* proteins. Notably, the cryo-EM structures of the T4P of the acidophilic hyperthermophile *Saccharolobus solfataricus* and neutrophilic hyperthermophile *Pyrobaculum arsenaticum* (Fig. 1(E)–(H)) revealed that the extensive glycosylation previously observed in the *Sulfolobus islandicus* pilus is a response to acidic environments rather than extreme temperatures, as at even higher temperatures but neutral environments, much less glycosylation is observed in *Pyrobaculum* than in *Sulfolobus* and *Saccharolobus* pili.

Attachment to pili-like filaments was also confirmed for *Sulfolobus* turreted icosahedral virus (STIV), the type member of the *Turriviridae* family, which specifically recognizes unidentified pili-like filaments of its host, *Saccharolobus solfataricus*. The icosahedral STIV virions are decorated with turret-like protrusions at each of the fivefold vertexes. A three-dimensional reconstruction of the STIV-pilus interaction using cryo-electron tomography displayed that the turrets physically interact with the *S. solfataricus* pilus. Furthermore, tomographic reconstruction and sub-tomogram averaging unequivocally showed that pilus recognition occurs at the cleft between the second and third jelly-roll domains of the pentameric turret protein C381. Notably, structurally similar jelly-roll

Fig. 1 Virus binding to archaeal type 4 pili. Representative cryo-electron (A) and negative staining (B) micrographs of the *P. arsenaticum* pili interacting with the hyperthermophilic virus Pyrobaculum filamentous virus 2 (PFV2). Scale bar, 20 nm in A and 200 nm in B. Orange arrowhead points to the *P. arsenaticum* pilus; blue arrowhead points to the PFV2 virion; green arrow points to the regions of the pilus-virion interaction. Representative cryo-electron (C) and negative staining (D) micrographs of the *S. solfataricus* pili interacting with the filamentous hyperthermophilic virus Saccharolobus solfataricus rod-shaped virus 1 (SSRV1). Scale bar, 20 nm in C and 200 nm in D. Orange arrowhead points to the *S. solfataricus* pilus; blue arrowhead points to the SSRV1 virion; green arrow points to the regions of the pilus-virion interaction. Cryo-EM reconstruction of the *P. arsenaticum* pilus at 3.8 Å resolution (E) and the *S. solfataricus* pilus at 3.4 Å resolution (F). Thin slices parallel to the helical axis of the pilus are shown, colored by the helical radius (G, H). Side view and top view of the *P. arsenaticum* and *S. solfataricus* pilus atomic models, built into the cryo-EM maps shown in E, F. The model is colored by chain. Image modified from Wang, F., Baquero, D.P., Su, Z., *et al.*, 2020. The structures of two archaeal type IV pili illuminate evolutionary relationships. *Nature Communications* 11, 3424.

domains have been implicated in receptor recognition in highly diverse viruses, including P22-like head-tailed phages (*Caudovirales*), tectiviruses and adenoviruses. Despite the molecular insights into the receptor binding, as in the case of SIRV2, it remains unclear how (and whether) the virus moves along the filaments and how circular virus genome is delivered into the host cytoplasm. Notably, adsorption to the pili of both SIRV2 and STIV was shown to occur exclusively at physiologically-relevant, high temperatures.

Interaction With Cell-Surface

Most archaea are surrounded by a thin proteinaceous surface layer (S-layer), consisting of glycosylated proteins anchored in the cell membrane. The S-layer is proposed to maintain an osmotic balance across the envelope, protect the cell from harsh environmental conditions and contribute to the cell shape. Notably, except for certain methanogens, archaea lack an equivalent of the bacterial peptidoglycan layer. The relative simplicity of the archaeal cell envelope likely underlies the mechanisms of virus entry and egress, and might have played a key role in shaping the virus diversity associated with archaea.

Spindle-shaped viruses of the *Fuselloviridae* family are often attached to membrane-derived vesicles or cellular fragments, suggesting that viral receptors are exposed on the host cell surface, with S-layer itself being a prime suspect. The spindle-shaped virion of the model fusellovirus SSV1 at one of the two pointed ends of the virion contains short terminal fibers, likely composed of protein VP4, which are postulated to mediate host recognition. Despite the observations suggesting possible interactions between SSV1 terminal fibers and the host cell surface, two recent studies on the *Sulfolobus* S-layer produced somewhat contradictory results regarding the role of S-layer for fusellovirus infection. On the one hand, the essential role of the S-layer in SSV1 infection appears to be supported by the finding that *Saccharolobus solfataricus* cells in which *slaB* encoding the membrane-anchoring S-layer protein was downregulated by a CRISPR-based silencing technology are less susceptible to SSV1 infection. On the other hand, cells in which both genes encoding the S-layer proteins *SlaA* and *SlaB* were deleted remained susceptible to infection with SSV9, a close relative of SSV1, suggesting that S-layer is not essential for either adsorption or infection by SSV9. These discrepant results call for additional studies focusing on the entry mechanism of fuselloviruses.

The entry process has also been explored for viruses infecting halophilic archaea. Insights have been obtained into the DNA ejection process in the halophilic spindle-shaped virus His1, the type member of the *Halspiviridae* family. Similar to fuselloviruses, at one of the pointed ends, His1 virion carries a putative receptor-binding module consisting of a central hub and six tail spikes. *In vitro* analysis demonstrated that His1 DNA ejection is unidirectional, occurs at a rate comparable to that of bacteriophage λ and is dependent on external osmotic pressure. Notably, *in vitro*, the His1 DNA ejection was only partial, suggesting that cellular factors are required for completion of the nucleic acid transfer. Interestingly, upon DNA ejection, the lemon-shaped virions transform into empty tubes, indicating that capsid proteins are capable of undergoing substantial quaternary structural changes.

Members of the family *Pleolipoviridae* have pleomorphic virions, which resemble membrane vesicles decorated with protruding spikes that in all likelihood participate in host attachment and membrane fusion processes. It has been suggested that upon binding to the receptor, the spike protein VP5 of Halorubrum pleomorphic virus 6 (HRPV-6) undergoes conformation change and drives fusion of the viral membrane with the host cytoplasmic membrane. Structural analysis of HRPV-6 virion by cryo-electron tomography and crystallography revealed that HRPV-6 VP5 has a unique V-shaped fold that is unrelated to the previously reported class I–III viral fusion protein.

The host recognition by archaeal head-tailed viruses appears to be mediated by tail fiber proteins, resembling the initial interactions of the bacteriophages of the order *Caudovirales*. Interestingly, the head-tailed dsDNA virus ϕ Ch1 infecting the haloalkaliphilic archaeon *Natrialba magadii* encodes a phase variation system. The system consists of an invertible region including a site-specific recombinase of the tyrosine recombinase superfamily interspersed between convergently oriented ORFs 34 and 36, which encode viral tail fiber proteins. Recombination in this region leads to an exchange of the gene fragments encoding the carboxy-termini of the tail fiber proteins, thereby creating a set of heterogeneous gp34 and gp36 proteins with distinct C-termini. Notably, only ORF34 is expressed during the virus infection indicating that fiber proteins of ϕ Ch1 are produced exclusively from this ORF. Binding assays showed that only one type of the heterogeneous tail fibers encoded by ORF34 interacts with *N. magadii*, suggesting that other tail fiber variants enable adsorption to other host strains. Galactose moieties present on the cell surface were implicated in host recognition by ϕ Ch1. Thus, as reported for bacterial viruses, the generation of two types of tail fiber proteins with distinct binding features might expand the ϕ Ch1 host range to quickly respond to habitat changes.

Kinetics of Virus Entry

There is a wide variation in terms of adsorption kinetics among archaeal viruses. Generally, hyperthermophilic archaeal viruses tend to display rapid adsorption rates, whereas halophilic viruses are notoriously slow. For instance, it has been shown that SIRV2 adsorbs very rapidly, with ~80% of the virions bound to the host cell within the first 30 s of infection. Similarly, ~50% of spindle-shaped SMV1 virions were attached to the cells within 1 min post-infection (p.i.). By contrast, only 30% of the salt-erprovirus His1 and siphovirus HHTV-1 virions adsorb to their host in 3 h. Similarly, the adsorption of the tailless icosahedral haloarchaeal virus HCIV-1 is rather efficient but slow, with the 80% of the particles adsorbed to cells at 4–5 h p.i. While the high adsorption rates of hyperthermophilic viruses are thought to minimize the time they are exposed to harsh extracellular conditions, including acidic pH and high temperatures, the low adsorption rates of haloarchaeal viruses are hypothesized to reflect an evolutionary adaptation to the long generation time of the hosts, whereby rapid adsorption might deplete the host population. Alternatively, it has been proposed that the changing salinity conditions of natural hypersaline environments may have favored the slow-adsorbing viruses that bind efficiently only under a specific range of salt concentrations.

Genome Replication

Very few studies have investigated experimentally the mechanisms of archaeal virus genome replication. In most cases, the mode of genome replication has been inferred from recognizable virus-encoded replication-associated genes, including rolling-circle replication initiation endonucleases (RCRE), DNA polymerases, replicative helicases and other components of the host replisome. Members of the families *Ampullaviridae*, *Thaspiviridae*, *Halspiviridae*, and *Ovaliviridae* as well as members of the genus *Gammapleolipovirus* (*Pleolipoviridae*) have linear dsDNA genomes and encode protein-primed family B DNA polymerases. By contrast, certain head-tailed haloarchaeal viruses encode RNA-primed DNA polymerases closely related to the corresponding proteins of their hosts. Generally, there is a correlation between the viral genome size and the completeness of the viral DNA replication machinery. Thus, viruses with small to

medium-sized genomes (5–50 kb) commonly encode only essential components of the replication machinery, with the rest of the components being recruited from the host, whereas viruses with large genomes (> 100 kb) appear to depend minimally on the host replisome, encoding nearly complete DNA replication machineries including DNA polymerases, proliferating cell nuclear antigen (PCNA), primases, replicative helicases, and homologs of the archaeal Orc1/Cdc6 replication initiators. Global analysis of dsDNA viral genomes demonstrated that replicative helicases are the most common replication proteins (75% of the genomes) in the dsDNA virus world. Indeed, some archaeal viruses with medium-sized genomes encode replicative minichromosome maintenance (MCM) helicases. Interestingly, phylogenetic analysis indicates that the *mcm* genes found in haloarchaeal, methanosarcinal, and methanococcal (pro) viruses were acquired from their respective hosts many times independently.

The RCRE are encoded by members of the *Pleolipoviridae* (genus *Alphapleolipovirus*) and *Sphaerolipoviridae* (genus *Betasphaerolipovirus*). However, experimental evidence for rolling circle replication, showing the presence of ssDNA replicative intermediates, has been obtained only in the case of sphaerolipovirus SNJ1. It has been shown that the SNJ1 RepA protein, an RCRE of the HUH superfamily, is indispensable for the genome replication of SNJ1. Closest homologs of SNJ1 RepA are encoded by plasmids of halophilic archaea, while more divergent homologs (13%–19% identity) are also identified in euryarchaea from the orders *Methanosarcinales* and *Thermoplasmatales*, as well as in ammonia-oxidizing archaea of the phylum *Thaumarchaeota*, underpinning a wide distribution of the SNJ1 RepA-like proteins across mobile genetic elements from diverse archaeal lineages. Interestingly, SNJ1 RepA also shares similarity with bacterial transposases of the IS91 family, which transpose via a rolling-circle-like mechanism, highlighting evolutionary connections between viruses, plasmids and transposons.

A divergent RCRE has been also identified in rod-shaped viruses of the *Rudiviridae* family. The protein has been structurally characterized and studied biochemically. *In vitro*, the Rep protein displays the expected nicking activity. However, its role in the viral genome replication remains unclear, because it does not seem to be expressed during the virus life cycle, at least, under laboratory conditions. Although genome replication has been most extensively studied for rudiviruses, the actual mechanism remains enigmatic. Members of the *Rudiviridae*, such as SIRV2, encode several proteins proposed to be involved in DNA replication, recombination and repair. Those proteins include the above mentioned Rep, an ssDNA-binding protein with a unique fold, a ssDNA-annealing ATPase, a Cas4-like ssDNA nuclease, a dUTPase, and a Holliday junction resolvase. Furthermore, yeast two-hybrid analysis showed that five SIRV2 proteins interact with the host DNA sliding clamp PCNA, known as a “molecular toolbelt” which interacts with multiple components of the host replisome. Presumably, SIRV2 recruits the host replication machinery for the assembly of the replisome on the viral DNA template. An immunofluorescence study of SIRV2 infected cells demonstrated that viral DNA synthesis is confined to a focus near the periphery of the cell. The study also provided evidence that the viral ssDNA-binding protein (gp17) as well as host PCNA and DNA polymerase I (Dpo1) are recruited to the site of viral DNA synthesis, confirming their essential role in the viral genome replication. Given that SIRV2 does not encode an identifiable DNA polymerase, the host polymerase Dpo1 found at the viral DNA synthesis site is likely to be involved in the replication of SIRV2 genome. An exceedingly complex model of SIRV2 replication has been proposed, whereby the virus employs a combination of strand-displacement, rolling-circle and strand-coupled replication mechanisms, which yields highly branched intermediates of about > 1200 kb (~34 viral genome units) with unusual ‘brush-like’ structures. However, it remains unclear how these three replication mechanisms are coordinated and whether all of them are essential for SIRV2 genome replication. In addition, the particular role of the host and viral proteins involved in the orchestration of viral DNA replication remains obscure.

It should be noted that most archaea-specific viruses do not encode identifiable DNA replication proteins, implying that these viruses either depend on the host DNA replication machinery or employ novel uncharacterized mechanisms for DNA replication. For instance, the genome replication of the lipothixvirus AFV1 has been suggested to start by the formation of a D-loop and progress by the strand displacement replication mechanism, whereas termination relies on recombination events through the formation of terminal-loop-like structures. However, the genes involved in this unique mechanism of replication are currently unknown. Similarly, the conspicuous absence of recognizable genes encoding type B DNA polymerases in viral genomes with linear dsDNA and terminal proteins, as in the case of the haloarchaeal sphaerolipoviruses PH1, SH1, and HHIV-2, suggests novel mechanisms of genome replication. A model resembling that of the *Streptomyces* linear plasmids has been proposed, whereby the cellular polymerase is employed for the viral genome replication and the terminal proteins are involved in the end patching of the DNA after replication.

Genome Integration

Many archaeal viruses are temperate and can undergo a lysogenic pathway in which they coexist with the host cell as proviruses. In most cases, the temperate viruses integrate their genomes into the host chromosome by the activity of viral site-specific integrases. However, sometimes proviruses can exist as circular extrachromosomal plasmids. For instance, the genomes of the euryarchaeal head-tailed virus ϕ Ch1 (family *Myoviridae*), pleomorphic virus SNJ2 (family *Pleolipoviridae*), and the crenarchaeal spindle-shaped SSV1 (family *Fuselloviridae*) integrate into the chromosome of *Natrialba magadii*, *Natrinema* sp. J7–1 and *Sulfolobus shibatae* cells, respectively, whereas the genomes of the sphaerolipovirus SNJ1 and myovirus ϕ H are stably maintained in a non-integrated circular form in *Natrinema* sp. J7–1 and *Halobacterium halobium* cells, respectively. Notably, the reactivation of the provirus typically occurs as a response to stressful conditions, such as DNA damage (e.g., by UV light or mitomycin C), temperature shock and shift from aerobic to anaerobic conditions. Depending on the virion release mechanism, the provirus induction can lead either to cell lysis, as for the head-tailed archaeal viruses and SNJ1, or to growth retardation, as observed for the fusellovirus SSV1 and pleolipovirus SNJ2.

Site-specific integrases of archaeal viruses, all belonging to the tyrosine recombinase superfamily, have been experimentally studied for two groups of viruses: fuselloviruses SSV1 and SSV2, and pleolipovirus SNJ2. The integrase of SNJ2 catalyzes homologous recombination between the viral attachment site located next to the integrase gene and the homologous site located within one of the tRNA genes on the host chromosome, leading to merger of the two genomes. Interestingly, integrases of fuselloviruses are unique in that the attachment site lies within the integrase gene itself and homologous recombination leads to disruption of the integrase gene into two fragments which flank the integrated provirus. Nevertheless, phylogenetic analysis has shown that SSV-like integrases have evolved from the more typical SNJ2-like integrases.

Transcription

Genomic analysis of archaeal viruses has shown a lack of genes encoding identifiable RNA polymerases as well as the presence of archaeal promoter elements, indicating a strong dependence on the host transcriptional machinery. However, the existence of putative transcription regulators in viral genomes suggests a viral-driven modulation to downregulate the host transcription and redirect the host transcriptional machinery towards the expression of specific viral genes in an efficient and temporal manner. Bioinformatics, biochemical, structural and transcriptomic efforts have provided valuable insights into the role of viral transcription regulators as well as into the modulation of the virus/host gene expression during the course of infection.

Transcription Regulators

A number of archaeal virus ORFs have been predicted to contain DNA-binding motifs typical of cellular transcription factors, with the majority displaying ribbon-helix-helix (RHH), winged helix-turn-helix (wHTH), or zinc (Zn) finger motifs. Notably, RHH and wHTH transcription factor sequences encoded by archaea and their viruses are bacterial-like, whereas archaeal Zn-finger domains share a common origin with those of eukaryotes. During the past years several virus transcription factors have been experimentally characterized and their structures have been solved. For instance, The AFV1p06 protein from the lipothrixvirus AFV1 is the first experimentally characterized archaeal Zn-finger protein. The protein preferentially binds to GC-rich DNA regions and displays a classical Zn-finger motif, albeit with an atypical substitution of one of the residues responsible for chelation of the Zn ion.

Most of the functionally characterized transcription regulators encoded by archaeal viruses are repressors, often also auto-regulating their own expression. For example, the transcription regulator SvtR encoded by the rod-shaped virus SIRV1 contains an RHH fold and forms a homodimer that resembles bacterial repressors CopG, NikR, and MetJ. Functional characterization of SvtR showed that its high-affinity binding-site corresponds to the promoter region of the *gp30* gene, which encodes a structural protein involved in the assembly of terminal fibers. Hence, it has been suggested that the primary function of SvtR is to prevent the premature expression of the structural protein encoded by *gp30*. Furthermore, SvtR binds to the promoter of its own gene (*gp08*), acting as a repressor and downregulating its own expression. The transcription regulator AvtR encoded by the filamentous virus AFV6 is highly conserved in the *Betalipothrixvirus* genus and consists of two RHH motifs connected by a linker. AvtR represses the expression of its own gene (*gp29*), but is able to both activate and repress the expression of the *gp30* gene in a concentration-dependent manner. Although in the case of both genes, AvtR binding sites are distant from the TATA boxes, DNase I footprinting assays showed that AvtR protects a region of approximately 100 nucleotides between the divergently oriented *gp29* and *gp30* promoters. This finding suggests that AvtR regulation depends on protein oligomerization on the DNA template. It has been proposed that AvtR binds to the initial binding site with high affinity and its oligomerization along the viral DNA induces cooperative binding to degenerate secondary sites with weaker affinity.

The transcriptional regulator F55 encoded by the fusellovirus SSV1 is one of the more extensively studied transcription factors encoded by archaeal viruses. Upon exposure to UV light, F55 plays a crucial role in the transition from the carrier to the induced state of SSV1. F55 is a dimer with an RHH DNA-binding motif. F55 recognizes tandem repeat sequences located within the promoters of the immediate early-induced transcripts T5, T6, and Tind as well as in its own promoter. Notably, binding of F55 to the target sequences leads to repression of the gene expression, whereas its dissociation causes activation of the transcription upon exposure of the SSV1 infected cells to UV light. A recent study using a variant of electrophoretic mobility shift assay (EMSA) coupled to mass spectrometry revealed that host RadA recombinase is associated with F55 when bound to the specific promoter sequences, forming a RadA-F55-dsDNA complex. The RadA recombinase belongs to the RecA/RadA/Rad51 protein superfamily and promotes DNA repair and recombination in hyperthermophilic archaea. Therefore, it has been proposed that RadA is a molecular sensor of the SSV1 host DNA damage analogous to the role of bacterial RecA protein in the life cycle of phage lambda. According to the proposed model, the exposure of infected cells to UV light causes massive DNA degradation that leads to accumulation of ssDNA regions. The RadA protein, which is coupled to F55 on the viral dsDNA genome, is recruited to the ssDNA regions and is progressively released from the RadA-F55-dsDNA complex, causing dissociation of F55 from the viral target sequences, thereby leading to activation of transcription of the immediate early transcripts. Notably, however, in vitro addition of ssDNA to the stable RadA-F55-dsDNA complex did not result in the release of the transcriptional block, prompting further studies to understand the specific role of RadA in the activation of the SSV1 transcription.

The regulation of the lysogeny has been also investigated for the haloarchaeal icosahedral virus SNJ1. The product of SNJ1 ORF4 has been recently suggested to controls the lysis-lysogeny switch. The expression level of ORF4 in the host cell appears to play a crucial role in the repression of genes responsible for the lytic pathway. Consistently, in absence of ORF4, SNJ1 produces

clear plaques, whereas in its presence, the plaques are turbid. In addition, ORF4 has been shown to play a key role in conferring immunity to the host cell against subsequent infections by SNJ1 (homotypic superinfection immunity) by repressing the genome replication of the superinfecting virus. ORF4 is conserved in other SNJ1-like proviruses, suggesting that the mechanisms behind the lysis-lysogeny switch and superinfection immunity is conserved in SNJ1-like proviruses.

Bicaudavirus ATV encodes an atypical transcriptional regulator, ORF145, which has apparently evolved from the major capsid protein, with which it shares significant sequence similarity. Similar to the major capsid protein, ORF145 is abundantly present in ATV virions. The protein binds to the host RNA polymerase (RNAP) with nanomolar affinity and inactivates it in a reversible manner via an allosteric mechanism. ORF145, renamed as RNAP inhibitory protein (RIP), binds apically to the DNA-binding channel of the RNAP and locks in a fixed position the RNAP clamp domain that typically switches between open and closed conformations during the transcription cycle. The high-affinity complex formed between RIP and the host RNAP inhibits the formation of transcription pre-initiation complexes and represses abortive and productive initiation as well as transcription elongation. Interestingly, RIP efficiently hinders the transcription directed from both host and viral promoters, suggesting a global inhibitory activity. Although the biological significance of a global transcriptional shutdown is unclear, it has been proposed that global repression prevents the host defense response. Notably, presence of RIP in the ATV virions suggests that host transcription might be repressed during the very early stages of the viral infection, most likely, to prevent the activation of the host type III-B CRISPR system.

Transcriptional Control

Whole-genome transcriptomic analyses using DNA microarray and RNAseq technologies have provided novel insights into virus–host interactions in crenarchaea. For example, SSV1 infected cells exhibit a tight chronological regulation of viral gene expression upon UV irradiation highly reminiscent of the strategy used by many bacterial and eukaryotic viruses. Thus, SSV1 temporal control leads to three clearly distinguishable sets of genes: immediate early, early and late genes. Transcriptomic analysis of the closely related virus SSV2 also displays a temporal regulation of gene expression which occurs in a distributive fashion with expressed genes not being adjacently located. Contrary to SSV1 and SSV2, analysis of gene expression of the lytic viruses SIRV2 and STIV display little temporal regulation of the viral gene transcription, with SIRV2 starting the transcription at multiple sites in the genome. Moreover, an RNAseq analysis on the two-tailed virus STSV2 shows that transcription of the majority of viral genes starts shortly after infection and increases throughout the infection cycle.

Studies on the host gene expression during virus infection showed that host response differs among archaeal viruses. While a small proportion of host genes was differentially expressed during the induction of SSV1 lysogens, the expression of several host genes encoding DNA replication, repair and transcription proteins was increased upon the infection with SSV2. Likewise, the transcription of more than one third of the *Sulfolobus* genes was differentially regulated as consequence of the SIRV2 infection. Notably, transcriptomic analysis of SIRV2 and STSV2 display a strong upregulation of antiviral defense genes including those for CRISPR-Cas and toxin-antitoxin systems. Consistently, infected *Sulfolobus islandicus* cells are actively undergoing CRISPR spacer acquisition from STSV2. These findings indicate that host response is virus-dependent since some viruses trigger a massive host response, whereas others, such as SSV1, are nearly unnoticed by the host. Interestingly, the same set of host genes can be up- and down-regulated by two different viruses, which suggests that distinct groups of host functions are required for the propagation of different archaeal viruses. For instance, the crenarchaeal cell division (*cdv*) operon, encoding homologs of the eukaryotic endosomal sorting complex required for transport (ESCRT) machinery, is downregulated upon SIRV2 and STSV2 infection but upregulated during the STIV infection.

Analysis of the host gene expression during virus infection also revealed significant upregulation of the host genes implicated in replication and DNA repair. The infection with fuselloviruses SSV1 and SSV2 leads to upregulation of genes encoding reverse gyrase, two subunits of the topoisomerase VI and the replication initiation protein Orc1/Cdc6, whereas the expression of the genes encoding the MCM helicase, PCNA and Dpo1 were boosted only in the case of SSV2. Similarly, reverse gyrase and Orc1/Cdc6-like genes were upregulated during the STIV infection, whereas genes implicated in energy production and metabolism were downregulated. The STSV2 infection leads to increased transcription of Holliday junction resolvase, DNA topoisomerase I and several DNA repair proteins, albeit the expression of the reverse gyrase, unlike for other crenarchaeal viruses, was downregulated. Differential regulation of genes encoding proteins involved in transcription suggests that viral transcription also relies on the host cell machinery. For instance, infection with SSV2, SIRV2 and STIV resulted in the upregulation of transcription initiation factor IIB, different subunits of the DNA-directed RNA polymerase and several transcriptional regulators.

Virion Egress

The last stage of the viral infection cycle corresponds to the egress of the new virions from the host cell. So far, release mechanisms have been studied in detail only for a handful of archaeal viruses. Generally, there are two types of archaeal viruses – those that disrupt the host cell upon virion egress (i.e., lytic viruses) and those that do not (i.e., non-lytic viruses). Similar to bacteriophages, some archaeal viruses can undergo a lysogenic life cycle in which the expression of most viral genes is suppressed and the virus is able to persist in the cell either as a provirus integrated into the host chromosome or as an episomal (extrachromosomal) element. In addition, some viruses can establish a carrier state, whereby the virus is stably maintained in a fraction of the cellular population, without causing cell lysis with the remaining cells being transiently resistant to the viral infection.

Cell Membrane Disruption

Lytic archaeal viruses have evolved several unrelated mechanisms for disruption of the cell envelope. The most extensively characterized mechanism involves formation of large pyramidal portals, dubbed virus-associated pyramids (VAP) (Fig. 2). VAPs develop on the surface of the infected cells, protrude through the S-layer (Fig. 2(A)–(D)) and open outward as flower petals (Fig. 2(E)–(H)), generating apertures through which the mature virions exit from the cell. This mechanism is used by viruses from at least three unrelated families, namely, *Rudiviridae*, *Turriviridae* and *Ovaliviridae*. VAPs of the rudivirus SIRV2 and turrivirus STIV exhibit seven-fold symmetry, while those of the ovalivirus SEV1 are six-sided. The VAPs consist of multiple copies of a single 10 kDa viral protein containing a transmembrane domain which promotes its insertion into the cellular membrane. Interestingly, heterologous expression of the SIRV2 pyramid protein P98 in archaeal (*Sulfolobus acidocaldarius*), bacterial (*Escherichia coli*) or eukaryotic (*Saccharomyces cerevisiae*) cells resulted in correct insertion into the membrane and formation of VAPs. Nevertheless, the signal triggering the opening of the pyramid structures appears to be archaea-specific since pyramids expressed in bacteria and eukaryotes were never observed in the open conformation. In addition, pyramidal structures have also been observed on the surface of an unidentified crenarchaeon, probably of the order *Thermoproteales*, infected with an unknown filamentous virus as well as on the surface of *Pyrobaculum oguniense* cells, suggesting that the VAP-based strategy is common among crenarchaeal viruses.

Head-tailed viruses infecting euryarchaea also lyse their host cells, but the underlying mechanism remains unknown. Bacterial relatives of archaeal head-tailed viruses lyse the cells using the holin–endolysin system, in which holin is a small membrane protein which forms lesions in the membrane, whereas endolysin is a peptidoglycan digesting enzyme. Phages infecting gram-negative bacteria often encode additional lysis proteins responsible for disintegration of the outer membrane. Thus far, homologs of the components constituting the holin–endolysin systems have not been identified in archaeal viruses. However, several viruses infecting methanogenic archaea, including siphovirus ψ M1 infecting *Methanothermobacter marburgensis*, encode pseudomurein endoisopeptidases which degrade the pseudomurein layer, which is equivalent, but not evolutionarily related to the bacterial peptidoglycan. Activity assays confirmed the cell wall-degrading activity of the pseudomurein endoisopeptidases which cleave the ϵ -isopeptide bond between alanine and lysine in the peptide chain of the pseudomurein. However, it remains unclear how these enzymes cross the cell membrane to reach the cell wall since no genes encoding potential holins have been identified in the genome of methanogenic viruses. Furthermore, pseudomurein is not universally present in euryarchaea or even methanogens. How head-tailed viruses infecting other archaea, such as halophiles, are released from the host remains unclear.

Lytic life cycle has been also demonstrated for filamentous enveloped viruses of the *Tristromaviridae* family which infect hyperthermophilic *Pyrobaculum* species (phylum *Crenarchaeota*). Electron microscopy analysis has shown that at the late stages of infection, the cells are packed with virions and their envelope is slashed by long, straight cuts not observed for other archaeal virus–host systems. However, the mechanism underlying this lysis mechanism has not been investigated.

Viral Release Without Membrane Disruption

Many archaeal viruses are released from the host without causing cell lysis. This type of virion egress has been most extensively studied on the example of fuselloviruses, in particular, SSV1. The assembly of SSV1 virions is concomitant with the egress and occurs by a mechanism that resembles the budding of enveloped eukaryotic viruses (Fig. 3). Dual-axis electron tomography analysis has shown that viral nucleoprotein complexes are extruded through the host cytoplasmic membrane in the form of tubular intermediate structures which share a continuous envelope with the host membrane (Fig. 3(A)). Subsequently, the SSV1 virions attached to the cell membrane undergo maturation to the characteristic spindle-shaped morphology. Formation of constricted ring-like structures (Fig. 3(B)) at the trailing end of the virion bud precedes the separation of the SSV1 virion from the cell membrane (Fig. 3(C)). The ring-like structures observed during the final step of SSV1 budding resembles the budding necks observed prior to the ESCRT machinery-mediated membrane scission during egress of some eukaryotic viruses, including human immunodeficiency virus and Ebola virus. The ESCRT system drives key membrane-remodeling processes in eukaryotes, such as cytokinesis, multivesicular body biogenesis and viral budding processes. Notably, proteins homologous to eukaryotic ESCRT components are conserved in several members of the *Sulfolobales* and play a central role in cell division, suggesting that, as for eukaryotic viruses, SSV1 budding may rely on a cellular membrane remodeling machinery. Similarly, pleolipoviruses have been suggested to possess a nonlytic life cycle and be released through a budding mechanism. Notably, however, unlike crenarchaea, halophilic archaea do not encode the ESCRT machinery.

Antiviral Defense and Viral Counterdefense Mechanisms

In most environments, viruses and their hosts are engaged in a constant evolutionary arms race. In this context, a broad range of host defense strategies as well as viral counterdefense mechanisms have been described in bacteria, whereas in archaea such mechanisms remain poorly understood, with the exception of the CRISPR–Cas system.

Fig. 2 Virus-associated pyramids (VAPs) in closed and open conformation. Tomographic slice (A, C, E, and G) and segmented, surface-rendered volumes (B, D, F, and H) of VAPs in the membrane of SIRV2-infected *S. islandicus* cells. VAPs are either closed (A–D) or open (E–H). The S-layer is purple, the cell membrane is blue, and the VAP is yellow. Scale bars, 200 nm. Antiviral Defense Mechanisms

Mechanistically, the defense systems of archaea and bacteria can be classified into three main groups: (1) variation of virus receptors, (2) innate and adaptive immunity and (3) dormancy and programmed cell death. The variation of virus receptors includes programmed changes, such as phase variation and physical masking of the receptor in order to hamper the successful binding of the virus to the host cell. Defense mechanisms that rely on immunity involve the recognition and inactivation of invader genetic material either by nonspecific innate immunity, such as restriction modification modules and Argonaute-based

innate immunity, or highly specific adaptive immunity, represented by CRISPR-Cas systems. Finally, strategies based on induction of dormancy or programmed cell death upon viral infection include toxin-antitoxin (TA) systems, in which the infection disrupts the balance of the host toxin-antitoxin complex leading to retardation of the cell growth or death. During the past few years the study of antiviral defense mechanisms in archaea has been focused on CRISPR-Cas systems, whereas hints about the role of toxin-antitoxin system in virus-host interactions has been provided by transcriptomic analysis of infected cells.

CRISPR-Cas systems

The CRISPR-Cas systems represent prokaryotic adaptive immunity mechanism present in about 40% of bacteria and almost all archaea. This system protects cells against invasion of mobile genetic elements, such as viruses and plasmids. CRISPR-Cas immunity involves three main stages: (1) adaptation stage, during which new virus/plasmid-derived sequences (spacers) are integrated into the CRISPR array adjacent to the leader sequence of the CRISPR array, (2) processing stage, during which the CRISPR array is transcribed and processed into separate CRISPR RNAs (crRNAs) containing the spacer sequence with 5' and 3' tags from the flanking repeats of the CRISPR array, and (3) interference stage, whereby the crRNA binds to the assembled CRISPR effector complex (interference module) to recognize and degrade DNA and/or RNA molecules containing the protospacer sequence. Based on gene synteny and the composition of the effector complexes, CRISPR-Cas systems have been divided into two classes, each subdivided into three types and several subtypes. CRISPR-Cas systems are very abundant among archaea and often several different types of CRISPR systems are encoded on the same archaeal genome.

It has been observed that SIRV2 infection leads to massive activation of the CRISPR-Cas systems present in *Sulfolobus islandicus* LAL14/1. The genome of *S. islandicus* LAL14/1 contains six CRISPR-*cas* loci encoding complexes of the three subtypes: I-A, I-D and III-B. The SIRV2 infection led to a sharp increase of the transcription levels of all CRISPR-*cas* arrays, except for one incomplete type III-B CRISPR-Cas module lacking the CRISPR array. Moreover, the expression of CRISPR arrays was activated immediately after SIRV2 infection and steadily increased during the course of the infection, with the highest levels of *cas* expression being reached 1 hpi. Notably, the expression levels of different CRISPR-Cas loci varied upon SIRV2 infection, suggesting their specialized roles during viral infection. The ability of SIRV2 to propagate in *S. islandicus* LAL14/1 despite the presence of active CRISPR-Cas systems carrying spacers matching the viral genome suggested the presence of viral anti-CRISPR (Acr) proteins which could counteract the host immune response. Similarly, a transcriptomic analysis on STSV2 infected cells revealed a differential expression level of the CRISPR-Cas systems upon infection. *S. islandicus* REY15A, the STSV2 host, encodes one type I-A and two type III CRISPR systems. Upon STSV2 infection, the type I-A module was strongly upregulated, whereas the expression level of one type III-B complex was downregulated through the course of STSV2 infection and the second type III-B complex was weakly upregulated. The interaction between tailed spindle-shaped virus SMV1 and the CRISPR-Cas systems of *S. islandicus* REY15A was studied in more detail by constructing strains carrying plasmid-borne mini-CRISPR arrays targeting SMV1 genome. The CRISPR response against SMV1 was type-specific, with the III-B CRISPR complex showing a tight control on the inhibition of the viral replication and proliferation during the infection, whereas the I-A CRISPR complex gradually lost the control of the viral proliferation allowing viral replication and release. The absence of SMV1 escape mutations conferring tolerance to I-A CRISPR system suggests that the virus has evolved a mechanism, probably an Acr protein, specific against the type IA CRISPR system.

Rudivirus SIRV3, a closely related virus to SIRV2, undergoes a host-dependent carrier state infection in *Sulfolobus islandicus* REY15A whereby the virus is maintained in a small fraction of the population over several days without apparent chromosomal DNA degradation, disturbance of the cell growth or induction of detectable CRISPR-Cas response. Notably, coinfection with the bicau-davirus SMV1 did not affect the SIRV3 carrier state and led to the coexistence of both viruses in the culture over 12 days, despite the induction of CRISPR spacer acquisition from SIRV3 DNA and the increased transcription of the subtype I-A CRISPR-Cas module. A plausible explanation for the maintenance of both viruses in the cell cultures seems to be that host CRISPR-Cas systems are inhibited by the virus-encoded Acr proteins encoded by SIRV3 and SMV1, which most likely target different types of CRISPR-Cas complexes encoded by the host. Transcriptomic analysis of *S. solfataricus* P2 cells infected with the fusellovirus SSV2 showed strong upregulation of the six CRISPR loci. By contrast, such effect was not observed when *S. solfataricus* P2 was infected with SSV1, a close relative of SSV2. Surprisingly, the co-infection with both viruses caused the silencing of the host CRISPR response. The major difference between SSV1 and SSV2 lies in the UV-inducible operon present in SSV1 but not in SSV2. Therefore, it has been speculated that SSV1 UV-inducible operon encodes transcription factors that may silence the CRISPR-Cas response in the SSV1-infected strain.

Interestingly, CRISPR-mediated defense systems appear to be employed not only by cells to defend against mobile genetic elements, but also by viruses for interviral conflicts. It was discovered that some archaeal viruses carry mini-CRISPR arrays (with 1–2 repeat-spacer units), which are preceded by promoter-containing leader sequences and genetic determinants required for insertion of new spacers. Remarkably, most of these virus-borne spacers target closely related viruses present in the same population. For instance, SPV1 and SPV2, two closely related viruses of the family *Portogloboviridae* isolated from a Japanese hot spring, were found to possess mini-CRISPR arrays with spacers reciprocally targeting each other. The existence of related viruses carrying mini-CRISPR arrays against each other in the same population suggests that viruses have adapted the host defense system for interviral conflicts and use it as a mechanism of heterotypic superinfection exclusion, in which a cell infected by one virus becomes resistant to another closely-related virus.

Toxin-antitoxin system

The toxin-antitoxin (TA) modules consist of a toxin protein capable of inhibiting the cell growth and an antitoxin that neutralizes the action of the toxin. TA modules can be encoded by both cellular organisms and mobile genetic elements, more commonly, plasmids

but also viruses. The toxin and its cognate antitoxin form a stable complex preventing the toxin from exerting its toxic effect in normally growing cells. Whereas toxin is a stable protein, often a nuclease, the antitoxin is typically labile, with quick turnaround, and has to be constantly synthesized. Under stressful circumstances, when the production of antitoxin is perturbed, the toxin is unleashed, leading to cell dormancy or death. Given that virus infection can lead to disbalance in toxin-antitoxin equilibrium, TA clusters have been proposed to represent a mechanism of abortive infection, in which an infected cell commits “altruistic suicide” to protect the population. Although the role of TA systems in virus-host interactions has been poorly understood in archaea, it has been suggested that *csa5* represents a toxin gene in the type I-A CRISPR system of *Saccharolobus solfataricus* P2, because Csa5 is toxic in the CRISPR-deficient *S. solfataricus* strain. Infection with rudivirus SIRV2 leads to induction of the Csa5 expression and formation of Csa5 oligomers in *Sulfolobus* cells, suggesting that Csa5 may be involved in programmed cell death in response to virus infections. Future work is required to gain insights into the mechanism of Csa5 toxicity and its biological relevance.

Transcriptomic analyses have revealed an upregulation of the type II TA systems upon viral infection. The type II TA systems are widespread among members of the order *Sulfolobales* and consist of an antitoxin protein that directly binds and inhibits the effect of a toxin protein. *S. islandicus* LAL14/1 encodes 16 operons of the family VapBC (virulence associated proteins B and C) and 6 operons of the family HEPN-NT (higher eukaryote and prokaryote nucleotide binding-nucleotidyltransferases), whereby the toxins are proposed to perform RNA cleavage. Notably, the expression of 11 out of 16 VapBC and 3 out of 6 HEPN-NT loci increased after SIRV2 infection at different time points. In most cases, the expression level of both genes coding the toxin and antitoxin was upregulated to similar extents. Likewise, bicaudavirus STSV2 infection caused a strong upregulation of the host TA gene pairs, including *vapBC*. Even though the role of TA operons remains unclear, the increase in TA gene expression after infection strongly suggests a function in host defense response.

Counterdefense Mechanisms

Viruses have evolved strategies to evade the targeting by host CRISPR-Cas adaptive immunity. The simplest mechanism involves mutations in the protospacer adjacent motifs (PAM), a short motif necessary for correct CRISPR targeting. A more sophisticated mechanism relies on the dedicated anti-CRISPR proteins (Acrs) which inhibit CRISPR-Cas by a diversity of mechanisms, including binding to specific subunits of the effector complexes. Although Acrs have been studied in many bacteriophages, only three archaeal Acr proteins have been characterized, despite the high abundance of CRISPR systems in archaeal genomes.

All three archaeal Acrs were discovered in rudiviruses, although some of them display much broader distribution. The AcrID1 protein inhibits subtype I-D CRISPR-Cas system by binding directly to the Cas10d subunit of the I-D CRISPR-Cas effector complex. The AcrID1-Cas10d interaction blocks the interference stage of the I-D CRISPR-Cas response in which the CRISPR RNAs (crRNAs) and Cas proteins form an effector complex that recognizes the viral sequence complementary to that of the crRNA spacer and cleaves it. Notably, AcrID1 is a conserved dimeric $\alpha\beta$ -sandwich protein widely distributed in viruses infecting hyperthermophilic crenarchaeota of the order *Sulfolobales*, including rudiviruses, lipothrixviruses, fuselloviruses, and monocaudaviruses, with about 50 homologs.

The two other Acr proteins disarm the type III CRISPR systems. Type III CRISPR-Cas systems exhibit a high complexity and consists of four subtypes (III-A–III-D), of which subtypes III-A (Csm) and III-B (Cmr) have been the most studied ones. In both cases, the type III effector complex binds to the viral protospacer causing the activation of the Cas10 protein as well as the synthesis of cyclic oligoadenylates (cOAs) from ATP. The presence of cOAs, in turn, triggers the activation of the Csm6 RNase in the III-A system and Csx1 in the III-B system to cleave the viral mRNA. It has been recently demonstrated that SIRV2 gp48, which is conserved in several members of *Rudiviridae* and *Lipothrixviridae*, is an Acr protein that exclusively inhibits the subtype III-B CRISPR-Cas system (AcrIIIB1) of *S. islandicus* LAL14/1. AcrIIIB1 was demonstrated to bind to two distinct effector complexes of the subtype III-B system, Cmr- α and Cmr- γ , suggesting that the mechanism by which AcrIIIB1 inhibits the subtype III-B response is by interfering with the Csx1 RNase activation process. The third archaeal Acr belongs to the DUF1874 protein family and was named AcrIII-1 family, because unlike all other known Acr of bacteria or archaea, it is not specific for a particular subtype, but blocks all subtypes of type III. AcrIII-1 is an enzyme with a ring nuclease activity, rapidly degrading the cyclic tetra-adenylate (cA₄) second messenger into a linear di-adenylate (ApA>P) with a cyclic 2',3'-phosphate, thereby preventing the activation of the type III-associated RNase and, therefore, blocking the host type III CRISPR defense system. Given that the target of AcrIII-1 is a signaling molecule (cA₄) with a constant structure, rather than specific CRISPR effector protein, this Acr is likely to be able to inhibit any type III CRISPR subtype using cA₄ as part of its activation. Consistently, the AcrIII-1 family is widely distributed in viruses infecting both archaea and bacteria as well as plasmids and proviruses.

Conclusions

Since the first archaeal virus was isolated in 1977, a considerable effort has been made to understand their virion architectures, genome contents and modes of interaction with their hosts. However, despite the substantial progress, a comprehensive understanding of molecular mechanisms that underlie these interactions is still lacking. The continued exploration of the archaeal virus diversity and development of new model systems, coupled with advances in molecular biology, genetics and microscopy tools are expected to shed further light on the mechanisms of virus-host interactions in archaea.

Glossary

Anti-CRISPR (Acr) genes Viral genes that code for proteins that interact with effectors of CRISPR-Cas systems to inhibit their antiviral immunity.

cOA signal transduction pathway Cyclic oligoadenylates (cOA) synthesized by type III CRISPR-Cas systems function as a secondary signal that bind to RNase of Csm6/Csx1 family to activate the enzyme for general cellular RNA degradation, leading to cell dormancy or cell death.

CRISPR-Cas systems The prokaryotic adaptive immune system that mediates small RNA-guided target nucleic acids destruction.

PAM-dependent DNA interference One of the CRISPR immunity mechanisms, in which CRISPR-Cas systems specifically recognize protospacer-adjacent motif to distinguish native versus foreign DNA and only target foreign DNA for destruction.

Transcription-dependent CRISPR interference Another unique CRISPR immunity mechanism, in which CRISPR-Cas systems rely on target transcription for mediating DNA interference.

Introduction

Archaea and bacteria coexist with mobile genetic elements (MGEs) such as viruses and plasmids in various environments. To maintain their ecological fitness, these microbes interact with viruses beneficially on one hand and develop antiviral mechanisms to prevent growth inhibition and cell death caused by harmful viruses on the other hand. These include the restriction and modification (R–M) systems, abortive infection, and toxin–antitoxin (TA) systems, prokaryotic Argonaute (pAgo), and most recently identified DNA phosphorothioate modification and virus replication inhibition systems, all of which provide innate antiviral mechanisms. About 12 years ago, antiviral immunity based on the clustered regularly interspaced short palindromic repeats (CRISPR)-Cas (CRISPR-associated) system was discovered, and it is present in about 90% of archaea and 40% of bacteria. To date, CRISPR-Cas represents the only adaptive immune system known for prokaryotes.

Archaea and bacteria often thrive in the same environments, and they exchange genetic materials via horizontal gene transfer. For this reason, it is not surprising that organisms of these two prokaryotic domains share many strategies of antiviral defense. To date, many bacterial antiviral systems have been studied in great detail, and this has facilitated the investigation of corresponding archaeal antiviral systems. In particular, important progress has been made in the study of archaeal CRISPR immunity due largely to the boom in CRISPR biology and CRISPR technology research in the past 12 years. Here, I mainly summarize the current understanding of archaeal CRISPR-Cas systems.

CRISPR-Cas: The Prokaryotic Adaptive Immune System

There are two genetic entities in CRISPR-Cas: CRISPR arrays carry repeats that are interrupted by unique short DNA sequences derived from viruses and other mobile genetic elements (protospacers) whereas *cas* gene cassettes code for structural proteins and enzymes. For antiviral defense, the immune system starts with searching for protospacers on invading viruses and incorporating them into CRISPR arrays as spacers during the first encounter. Upon a subsequent encounter, small RNAs generated from the acquired spacers guide the immune system to specifically recognize the corresponding protospacers and target the viruses for destruction.

Genes coding for Cas proteins are grouped together for each system, forming *cas* gene modules. Although distantly related Cas proteins can share limited or no sequence similarity, those of the same functional category have adopted very similar structures. At present, CRISPR-Cas systems can be categorized into two broad classes and six main types based on their gene synteny, sequence similarity of Cas proteins, and mechanisms of interference. Class 1 CRISPR-Cas systems employ multisubunit effector complexes to mediate CRISPR interference such as the systems belonging to types I, III, and IV, while those of class 2 rely on a single multidomain protein to perform the same function, including types II, V, and VI.

By now, it has been demonstrated that type I, II, and V systems target DNA for destruction whereas those of type VI show RNA interference (RNAi). Furthermore, type III CRISPR systems exhibit multiple CRISPR interference activities, including dual DNA and RNA interference and activation of a signal transduction pathway with cyclic oligoadenylates (cOAs) as the second messenger to activate Cas-accessory RNases, leading to indiscriminate cellular RNA degradation. Our current understanding on molecular mechanisms of archaeal CRISPR-Cas systems is summarized below.

Spacer Acquisition and its Regulation in Archaea

Spacer acquisition is the first step toward the generation of adaptive CRISPR immunity in prokaryotes. The process involves two core proteins, Cas1 and Cas2, that form a hexameric integrase. The enzyme complex contains four subunits of Cas1 and two

subunits of Cas2. It interacts, on one hand, with the first repeat of a CRISPR array and on the other hand, binds to a protospacer, a DNA segment derived from invading nucleic acids. In the end, the integration reaction adds the DNA segment into the CRISPR array at the end of the first repeat, forming the new first spacer. For this reason, the order of spacers in CRISPR arrays provides the chronological record of previous infections on the host chromosome by viruses and other genetic elements.

Archaea and bacteria often contain additional genes in the same locus of *cas1* gene. For example, in the genomes of *Sulfolobus* species, *cas1* and *cas2* are clustered with three other genes, *csa3a*, *csa1*, and *cas4*, forming the adaptation Cas (aCas) module. In this module, *csa3a* is the first gene and codes for a transcriptional factor. Based on the gene organization, Csa3a may function as a regulator to control expression of all aCas genes in the operon. Indeed, Csa3a activates not only the expression of aCas genes but also an array of DNA repair genes. Since bacterial DNA repair proteins are shown to be involved in protospacer selection, these archaeal DNA repair proteins are implicated in the same process.

Csa3-like transcriptional factors are interesting since they carry a ligand-binding domain called CRISPR-associated Rossmann fold (CARF). Other CARF-containing CRISPR-accessory proteins include Csm6 and Csx1 RNases associated with type III CRISPR-Cas systems. Type III systems catalyze the synthesis of cOA second messenger that interacts with the CARF domain of Csm6/Csx1 RNases (see below). However, the ligand that binds to the *Sulfolobus islandicus* Csa3 CARF domain remains to be identified.

Proteins encoded by remaining two genes (*csa1* and *cas4*) belong to the so-called Cas4 superfamily. Cas4 proteins interact with Cas1 and specify the upstream protospacer adjacent motif (PAM). Together they define the spacer length and recognize a downstream motif to ensure proper generation of pre-spacers as well as functional spacer integration. They are essential for efficient spacer acquisition in archaea. Strikingly, *cas4* genes are not only widespread on archaeal and bacterial chromosomes; viruses and plasmids can also code for such proteins albeit they are only distantly related to those present in aCas modules. Possibly, these viral Cas4 proteins can also interact the CRISPR acquisition machinery to downregulate the spacer acquisition or producing nonfunctional spacers to unarm the CRISPR immunity. For this reason, the virus-encoded Cas4 proteins can be classified as anti-CRISPR proteins at the stage of spacer acquisition.

Expression of CRISPR Loci and crRNA Biogenesis

All CRISPR loci show polarity as they provide a fossil record of MGE infection on the host chromosome. At the proximal end, there is a leader sequence that specifies the site for incorporation of new spacer as described above. This leader region also contains a promoter that drives the expression of the entire CRISPR array, producing precursor crRNAs. CRISPR loci can carry hundreds of spacers from which leader-proximal spacers are generally expressed to a high level. Nevertheless, there are also exceptions since crRNAs generated from some leader-distal spacers can also be very abundant. There are two possible reasons for the differential expression. First, spacers can carry promoter-like sequences (internal promoters) that increase the expression level of their downstream spacers; second, some DNA-binding protein may interact with CRISPR loci and modulate their expression such as the *Sulfolobus solfataricus* CRISPR-repeat binding protein. Since CRISPR loci are generally expressed to a high level in archaea, the significance of the modulated CRISPR expression remains elusive.

After transcription, the resultant precursor crRNAs are processed by a specialized enzyme of the Cas6 endonuclease family, producing small RNAs of single repeat-spacer unit. Although some bacterial CRISPR-Cas systems also employ other Cas proteins for crRNA processing, all known archaea only utilize Cas6 for crRNA biogenesis. In fact, many archaea contain several CRISPR-Cas systems and more than one *cas6* gene. For example, *S. solfataricus* has six CRISPR loci with two families of repeats, four *cas6* genes, and three different types of effector complex. The encoded processing enzymes show optimal activity to distinct repeat sequences and this scenario fits with the specific crRNA processing for different types of antiviral immunity. Nevertheless, *S. islandicus* REY15A has only one *cas6* gene although this archaeon contains three active CRISPR systems. Thus, this *cas6* is responsible for production of crRNAs to be used by all three immune systems. Furthermore, since the sizes of crRNAs are different for these antiviral systems, crRNAs generated by Cas6 are further processed and the mechanism of crRNA maturation can be type-specific.

Archaeal Type I CRISPR-Cas Systems

Bioinformatics analysis has revealed eight subtypes of type I CRISPR-Cas systems (I-A through I-G, I-U) among which I-A, I-B, I-C, I-D, I-E, and I-G are found in archaea. CRISPR-Cas systems of 3 type I subtypes are characterized in archaea, including I-A systems of *S. solfataricus*, *S. islandicus*, *Aeropyrum pernix*, and *Pyrococcus furiosus*, and I-B and I-G systems of *Haloferax volcanii* and *P. furiosus*, respectively (Fig. 1). These archaeal systems code for four structural Cas proteins: Cas7 is a backbone subunit that is present in multiple copies and binds to crRNA; Cas5 interacts with the 5'-handle of crRNAs; Cas11 is a small subunit interacting with Cas7 and crRNA; whereas Cas8, the largest subunit, interacts with Cas5 and Cas7 and functions in PAM recognition. They also code for their own Cas6 to generate mature crRNAs and Cas3 to mediate DNA interference. Cas3 is the type-specific Cas protein of type I systems. For most type I systems, the enzyme harbors a helicase and a nuclease domain but in I-A systems, the two domains are split into two proteins, denoted Cas3' and Cas3'' that contain the helicase domain and the nuclease domain, respectively.

Cas proteins of type I systems are known to form CRISPR-associated complexes for antiviral defense (CASCADE) to mediate antiviral immunity. Two basic types of CASCADE complexes are known for type I systems: Those represented by *Escherichia coli* I-E system are not associated with Cas3, and the enzyme is recruited into the CASCADE upon recognition of a PAM before DNA

Fig. 1 Gene organization of three type I subtypes of CRISPR-Cas systems. I-A: *S. islandicus* I-A module; I-B: *H. volcanii* I-B system; I-G: *P. furiosus* I-G module. For I-A and I-G systems, their backbone subunits (Cas7) are also called Csa2 and Cst2; large subunits (Cas8) as Csa4 and Cst1, respectively. Small subunit (Cas11) is only present in I-A, i.e., Csa5.

silencing. In I-A subtype systems, Cas3' and Cas3'' are integrated parts of CASCADE as shown for *A. pernix* and *P. furiosus* I-A systems. The other studied archaeal type I systems are *H. volcanii* I-B system and *P. furiosus* I-G complex, and they resemble the I-E effector of *E. coli*. To date, the structure of archaeal type I CASCADE remains to be determined.

Nevertheless, biological function of archaeal type I CRISPR-Cas systems has been demonstrated by using interference plasmid assay (also called invader plasmid assay). In this approach, an interference plasmid was constructed carrying a protospacer that matches one of the spacers in the chromosomal CRISPR arrays. Further, the plasmid also carries a PAM sequence that is absent from CRISPR loci in the host genome. Both interference plasmids and reference plasmids were introduced into archaeal cells by transformation, and the former showed 100–1000 folds of reduced transformation efficiency compared with the latter. Further, all transformants on plates were found to have lost the I-A CRISPR immunity either due to spontaneous deletion of targeting-spacer, or plasmid rearrangement, or mutation of a I-A *cas* gene. They are called escape mutants. Moreover, since PAM is absent from the spacer on the chromosomal CRISPR array, self-targeting by CASCADE is therefore avoided. The mechanism of the *S. islandicus* I-A DNA interference is illustrated in Fig. 2.

Archaeal Type III CRISPR-Cas Systems

Four type III subtypes of CRISPR-Cas systems are known: III-A, III-B, III-C, and III-D among which III-A and III-D are also called Csm systems whereas III-B and III-C are called Cmr systems. While III-A systems dominate in bacteria, III-B systems are primarily found in archaea. To date only a few archaeal type III systems have been characterized, and these include Cmr systems of *P. furiosus*, *S. solfataricus*, and *S. islandicus*, Csm systems in *Thermococcus onnurineus* (III-A) and *S. solfataricus* (III-D) (Fig. 3).

The first characterized type III effector is the *P. furiosus* Cmr ribonucleoprotein complexes, and it specifically cleaves target RNA. By now, a number of III-B effectors have been characterized. These effector complexes contain six different subunits (Cmr1 through Cmr6) among which Cmr1, 4, and 6 are backbone subunits possessing the Cas7 fold; Cmr3 has the Cas5 structure; whereas Cmr2 and Cmr5 are the large and small subunits, respectively. Each system forms effector complexes of two distinct sizes: The larger one has the subunit stoichiometry of Cmr1₁2₂3₂4₄5₃6₁ carrying a crRNA of 46 or 45 nt while the smaller one has three Cmr4 and two Cmr5 subunits with a shorter crRNA (40 or 39 nt). The two complexes share the same general structure: Cmr4 and Cmr5 form the core backbone in which Cmr4 subunits are packed in a head-to-tail fashion. The backbone is capped with Cmr2 and Cmr3 at the head and Cmr6 and Cmr1 in the tail. The crRNA passes through the entire effector complex. Furthermore, Cmr2 and Cmr3 form a heterodimer that binds specifically to the 5'-handle of crRNA, whereas the tail subunits are loosely associated with the core helix. This arrangement in the ribonucleoprotein (binary effector) complex ensures the flexibility for the tail to mediate target RNA capture to yield the ternary effector complex that is active in multiplex interference activities, including target RNA cleavage, RNA-activated DNA cleavage, and synthesis of cOA second messenger.

Target RNA cleavage by archaeal type III-B effector complexes is featured with 6 nt periodicity as for other type III systems. When some of their structures are resolved, it becomes clear that the active sites of RNA cleavage are located on Cmr4. Once target RNAs are cleaved and released from the effector complex, the immune system returns to the binary status that is inactive in DNA interference.

Transcription-dependent DNA interference by the Cmr effector relies on two activities: The RNA-activated DNA cleavage and synthesis of cOAs, both of which are conducted in Cmr2, the large subunit belonging to the Cas10 family. The involved mechanism is summarized as follows: (1) transcription of a target DNA produces cognate target RNA (CTR) that will bind to the effector in the process of target RNA capture; (2) interaction between crRNA and its CTR (that shows mismatches between the 3'-anti-tag of target RNA and the 5'-handle of crRNA) induces conformation changes in the effector to activate the Cmr2 HD motif for DNA cleavage; (3) in the meantime, Cmr2 is also activated for the cyclase activity to produce cOA, which functions as a second messenger to activate Csx1/Csm6 family proteins for cellular RNA destruction to yield cell dormancy or cell death; and (4) target RNA cleavage and release restores the inactive form of Cmr effector complexes (Fig. 4).

Fig. 2 Schematic of antiviral defense by the *S. islandicus* I-A system. Gene organization of I-A module (type I-A) and adaptation cas module (aCas) as well as two CRISPR loci (with 115 and 93 repeats, respectively) in *S. islandicus* are shown on the top. Transcription of CRISPR loci yields precursor CRISPR RNA (pre-crRNA) that is processed by Cas6 endonuclease to yield short crRNAs with a single spacer (crRNA). Expression of I-A cas genes give I-A Cas proteins including Cas3' nuclease and Cas3'' helicase. I-A Cas proteins and crRNA form ribonucleoprotein (type I-A RNP) complex. In the interference stage, the effector scans for target DNA site on ds-DNA, once a protospacer is found, the large subunit (Cas8) recognizes the CCN protospacer adjacent motif and authenticates the immune response. Cas3' helicase unwinds double-stranded DNA and Cas3'' nuclease cuts the target DNA sequence to yield target DNA silencing.

Fig. 3 Gene organization of type III subtypes of CRISPR-Cas systems. Four subtypes (III-A, -B, -C, -D) and one variant, III-Bv, are identified by analysis of gene synteny and sequence similarity of Cas proteins. Representatives of all subtypes except III-C have been characterized. III-B and III-C are also called Cmr systems and III-A and III-D, Csm systems. Annotations of individual subunits are given and their types of Cas proteins are also indicated: 10-Cas10, 7-Cas7, 5-Cas5, and S-small subunit. Cas10 is the type-specific protein and the most conserved Cas protein in this type of CRISPR immunity.

Fig. 4 Schematic of antiviral defense by the *S. islandicus* III-B Cmr-α system. Gene organization of adaptation cas module (aCas) and the III-B Cmr-α module as well as two CRISPR loci (with 115 and 93 repeats, respectively) in *S. islandicus* shown on the top. Transcription of CRISPR loci yields precursor CRISPR RNA (pre-crRNA) that is processed by Cas6 endonuclease to yield short crRNAs with a single spacer (crRNA). Expression of III-B *cmr* genes give 6 Cmr proteins. Cmr proteins and crRNA form ribonucleoprotein (III-B RNP) complex. Transcription of target gene produces mRNAs containing the cognate target RNA. Cmr1 mediates target RNA capture at the seed sequence region and base pairing between the crRNA and the target RNA yield major conformation changes to yield a ternary Cmr-α complex. Mismatches between the 5'-handle of crRNA and the 3'-anti-tag of target RNA authenticate the CRISPR immunity including RNA-activated DNA cleavage and synthesis of cOA second messenger. cOA binds to the CARF domain of Csx1 and activates its RNase from the HEPN domain to indiscriminately cleave viral and cellular RNAs in the cOA signal transduction pathway.

To date, all known type III systems possess both activities even though each activity is theoretically sufficient to mediate type III antiviral immunity. The current hypothesis is the cOA pathway is required for silencing a large amount of invading nucleic acids while the DNase is essential for final clearance of MGEs.

Among the three Cmr activities, the third activity, target RNA cleavage, mainly functions in the spatiotemporal control of the indiscriminate DNase and cOA synthesis. This mechanism ensures that the indiscriminate destruction of cellular DNA and RNA by type III immunity is only allowed to be active during a very brief time period. Prompt target RNA cleavage and cleavage product release readily inactivate Cmr effector. This provides an important mechanism to recover from cell dormancy or even cell death that would otherwise be induced by an uncontrolled type III immune response.

CRISPR arrays are also transcribed on the antisense strand, producing countertranscripts that show the full sequence complementarity with crRNAs including the 5'-handle, called noncognate target RNA. As a result, these target RNAs cannot trigger DNA cleavage and cOA synthesis, providing the mechanism of self-immunity avoidance.

Effective control of type III CRISPR-Cas immunity also requires to inactivate cOA second messenger. *S. solfataricus* code for ring nucleases that specifically degrade cOAs. As for Csx1 and Csm6, ring nucleases are also CARF proteins but they do not possess any conventional nuclease activity. Rather, they have a different CARF pocket that not only binds to cOA but also cleaves the messenger molecule in a metal-independent manner. In a Csx1 RNA cleavage assay, the ring nuclease effectively deactivates the Csx1 nuclease by competitively removing cA4 in the reaction.

Novel Archaeal CRISPR-Cas Systems

More recently, search for CRISPR-Cas systems in metagenomic databases reveals that archaea also code for class 2 CRISPR-Cas systems. These include two type II systems identified in nanoarchaea: One carrying *cas1*, *cas2*, and *cas4* for spacer acquisition with a *cas9*-like gene for interference as well as a hypervariable CRISPR array, and the other including 24 different *cas14* variant genes of three subgroups identified in uncultivated archaea. These are a unique group of archaeal organisms that form symbiosis with other organisms and are characterized by small cell size and genome size. Their type proteins, named Cas14, have 400–700 amino acids and therefore are much smaller than those of bacterial class 2 systems (950–1400 aa). *Trans*-acting CRISPR RNAs (tracrRNA) are also identified from transcriptome metagenomic data, and this rendered it possible to reconstitute Cas14 effector complexes in *E. coli* and study their antiviral immunity. Interestingly, Cas14 is capable of binding to ssDNA and mediate discriminate ssDNA cleavage. This novel type of CRISPR immunity is only present in archaea so far.

Anti-CRISPR Proteins of Archaeal Viruses

Viruses code for proteins that are able to counteract the CRISPR immunity, allowing viruses to proliferate in their hosts. These anti-CRISPR (*acr*) genes are widely present in bacterial and archaeal viruses, mediating resistance to immunity of CRISPR-Cas systems of types I, II, and V. In archaea, anti-CRISPR activity has been investigated for *Sulfolobus* viruses. Although remaining to be identified, the *Sulfolobus* SMV1 codes for Acr-IA proteins since it is resistant to the type I-A immunity in *S. islandicus* Rey15A. The first archaeal *acr* gene was identified in SIRV2 and SIRV3, the lytic rudiviruses. These viruses can infect *Sulfolobus islandicus* LAL14/1 despite the presence of functional CRISPR-Cas subtypes I-A, I-D, and III-B systems and spacers complementary to their genomes. Further studies reveal that the SIRV3 *gp02* gene encodes a protein (Acr-ID1) that interacts with the I-D Cas10 and inhibits the I-D immunity. Interestingly, Acr-ID1 has as many as 50 homologs in archaeal viral genomes. Possibly, archaeal viruses code for even more Acr-IA and Acr-IIIB proteins since these CRISPR-Cas systems are more prevalent in this prokaryotic domain.

Archaeal Innate Antiviral Systems

As in bacteria, innate immune systems in archaea include abortive infection, R–M systems, pAgo, and TA systems identified by comparative genomic studies, but most of these innate antiviral systems remain to be investigated. Nevertheless, a few representatives have been characterized, including the *Sulfolobus acidocaldarius* Sual R–M system, *Pyrococcus furiosus* Argonaute (PfAgo) and TA system, and the *H. jeotgali* DNA phosphorothioate modification and virus replication inhibition system. Here I briefly introduce the last three systems since the Sual R–M system functions as the well-known bacterial ones.

In eukaryotes, Agos function as a key enzyme in the RNAi pathway, and they target RNA transcripts using short 5'-phosphorylated RNA as guides. Their prokaryotic homologs, pAgos, are present in about 32% of archaea and 9% of bacteria. PfAgo shows DNA-guided DNA cleavage activity and the system reduces plasmid formation rate in *P. furiosus* by 30%–50%. Nevertheless, how archaeal Ago proteins function in antiviral defense remains to be investigated.

Archaea code for an arsenal of TA systems, for example, *Sulfolobus islandicus* Rey15A and LAL14-1 code for 21 or 22 TA systems, and many of them are homologs. This high homology has strongly hindered their functional characterization since their activity can only be revealed when all other homologous systems are inactivated in the same archaeal host. Nevertheless, some distantly related *P. furiosus* TA systems function as selection makers in *Pyrococcus yayanosii*. This represents the first example of genetic demonstration of archaeal TA systems that function in inducing programmed cell death. Therefore, archaeal TA systems function under the same principle as for their bacterial homologous systems.

A completely novel archaeal defense system was identified in *Haloterrigena jeotgali*. It consists of the genes homologous to the bacterial *dndCDEA* system that mediates phosphorothioate modification and the PbeABCD system that functions in halting virus propagation via inhibition of DNA replication. This unique combination allows the haloarchaeon to inhibit virus infection, and the defense system is conserved in several archaea.

Future Perspectives

Archaea and bacteria have devoted a large portion of their coding capacity for an arsenal of antiviral defense systems, including R–M systems, abortive infection, TA systems, archaeal Ago, DNA phosphorothioate modification, and virus replication inhibition systems, as well as the prokaryotic adaptive immunity encoded by CRISPR-Cas systems. These antiviral mechanisms constitute multiple layers of virus defense network, allowing archaea to effectively defend invasion of mobile genetic elements. Furthermore, many archaea carry multiple CRISPR-Cas systems that utilize very different immunity mechanisms to protect their hosts against invasion of nucleic acids. This raises important questions such as: How do these antiviral systems cooperate in the immune defense? Why are they all required in the arms race between microbes and their genetic elements? As it is now well established that genetic elements play important roles in horizontal gene transfer and evolution as well as in the maintenance of biodiversity on the Earth, these antiviral systems may contribute to fine-tuning of the arms race between archaea and their viruses, which in turn yields optimal horizontal gene transfer to increase the ecological fitness of archaeal organisms during evolution.

Introduction

High-temperature environments have intrigued life scientists ever since the first hyperthermophiles were discovered in the hot spring of Yellowstone National Park USA (YNP) in 1966. Since then the microbial communities of hot springs in YNP, as well as other high-temperature environments from around the world, have been extensively studied resulting in the discovery of archaeal and bacterial thermophilic (organisms with a growth optimum of 60–80°C) and hyperthermophilic (organisms with a growth optimum of > 80°C). Surprisingly, no hyperthermophilic eukaryotic species have been identified. While high-temperature environments can support both bacterial and archaeal microbial communities, high-temperature acidic environments (pH < 4) tend to be dominated by archaeal species.

Viruses are ubiquitous with cellular life. In any environment where cells are replicating, one is likely to find viruses associated with those cells. Not surprisingly, in archaeal dominated high-temperature environments, archaeal viruses are expected to be present. However, in part due to the limited number of archaeal species that have been cultured, we know of only a limited number of archaeal viruses from cultured-based studies. In order to overcome this limitation, virologists have increasingly turned to viral metagenomics, the deep sequencing of viral communities directly from environmental samples, to assess viral diversity and to assemble viral genomes. These studies have greatly expanded our knowledge of archaeal viruses in extreme environments, especially with regards to their diversity and unique adaptations for replication in high-temperature environments. There are presently 93 complete archaeal virus genomes deposited at NCBI (June 2019), and many more are expected in the coming years.

Regardless of the geographic location, it is the underlying geochemistry of the hot spring that determines the microbial and virus community structure. That is because these are chemolithotrophic dominated microbial communities which derive their energy from the oxidation of reduced inorganic compounds such as ammonia, ferrous iron, hydrogen sulfide, or hydrogen. Beyond temperature, sulfate levels and pH are major parameters that influence the microbial and virus community composition. As sulfide oxidation decreases pH, the resulting acidity may leach certain trace elements (Fe, Al, Co, Pb, Cd, V, and others) from rock and sediment through which geothermal water passes to reach the surface or from recirculating acid-sulfate water. Likely due to the energy constraints for microbial life, high-temperature low-pH hot springs typically support low cell densities (typically < 10⁶ cells/ml) and low free virus particle concentrations (typically < 10⁵ particles/ml). Cellular and viral metagenomic studies of these environments have revealed relatively simple microbial communities usually consisting of < 10 archaeal species and viral communities made up of ~ 100 different viral types. An additional benefit of these systems is the fact that viruses are the only microbial predator in these hot springs creating microbial systems where the role of viruses can be directly examined. These simplified cellular and viral communities provide a tractable natural system where host-virus interactions can be examined in detail.

Archaeal viruses remain enigmatic biological entities. They are the least characterized group of viruses as compared to viruses infecting Bacteria and Eukarya. Despite having only a limited number of characterized archaeal viruses, they possess a surprising diversity of virion morphologies and viral gene content. This is especially true for archaeal viruses present in hot springs. Archaeal viruses have been isolated from only two of the 18 proposed or recognized archaeal phyla. All known archaeal viruses from hot springs infect members of the Crenarchaeota, while archaeal viruses from high salt environments infect Euryarchaeota. This bias towards these two phyla is likely only a function of the environments in which archaeal viruses have been most searched for. It is likely that all phyla of Archaea support viruses. More recently, metagenomic studies have identified viruses predicted to infect other archaeal phyla but none of these viruses have been isolated to date. In addition to the two phyla with cultured viruses described above metagenomic studies have identified viruses predicted to infect four additional phyla: candidatus Bathyarchaeota, Nanoarchaeota, candidatus Nanohaloarchaeota and Thaumarchaeota.

Below we discuss the advantages and challenges of using metagenomics to identify and characterize archaeal viruses from high temperate environments. First, we review the practical considerations for collecting and processing viral samples for metagenomic analysis from hot spring environments. Next, we discuss the important variables to address in next generation sequencing (NGS) and sequence analysis that are unique to archaeal viral metagenomic studies. Finally, we review the major findings of applying metagenomic and other culture-independent tools in understanding archaeal virus community structure and function in hot springs ([Fig. 1](#)).

Sample Collection and Processing

Acidic terrestrial hot springs offer both unique advantages and challenges for investigators. The harsh chemical and physical environment selects for a small number of specific cell types, and thus their viruses. This selection can be leveraged to address

Fig. 1 Work flow of combined culture-dependent and culture-independent approaches to achieve virus characterization, including host identification, from hot spring environments.

complex ecological questions in a naturally simplified community. However, these same conditions present a number of difficulties ranging from personnel safety to technical challenges such as low host and virus densities and preventing acid hydrolysis of biomolecules.

Sampling terrestrial thermal fields requires preplanning and sampling by trained, experienced personnel with appropriate safety gear. It is essential to plan in advance the specific purpose for which the sample will be later utilized. For example, the sampling strategy for culturing new host and viruses is different from the sampling strategy required for the isolation of environmental nucleic acids. Sample site selection is also critical and dependent on the purpose of the sampling. Many thermal features are ephemeral, thus if long term temporal sampling on the time frame of years is required, appropriate site selection is critical. Furthermore, most thermal fields have a variety and fluctuating set of geochemical conditions. From a practical consideration, field measurements of temperature, pH and conductivity can be valuable in choosing an appropriate hot spring to sample. Hot springs, especially acidic hot springs, can be dangerous places to sample due to often turbulent super boiling acid waters and demineralization of the soils present in thermal fields. Walking in thermal areas is often more akin to traveling on glaciers, however in thermal areas the crevasses are boiling acid and steam. Sampling tools, including but not limited to extendable sampling poles, protective clothing, eyewear, and boots are important for safe sampling.

In planning a field sampling trip, one should consider what to sample and how to treat the sample until they are processed in a laboratory. Hot spring sediments often provide a rich source of cells while hot spring waters typically provide a better source of virus particles. Most acidic hot springs create environments where DNA that is not protected within a cell, or within a virus particle is rapidly hydrolyzed, therefore it is important to maintain cell and virus integrity during sampling. Furthermore, the low cellular and viral density present in most hot springs necessitates sampling large volumes, typically 1–100 L. If perfectly preserving a time-critical snapshot is necessary, then a small volume sample can be flash-frozen in liquid nitrogen. For large samples, transporting the samples at ambient temperature is ideal, especially if samples can be further processed within 24 h.

Isolation of cellular and viral fractions from hot spring samples is typically a multistep process. Clay particles are often present in samples and are removed by very low g centrifugation ($< 500 \times g$), which maintains the cells and viruses in solution. Separating the cells and intracellular viruses from free virus particles is accomplished by size filtration through a 0.45 μM and or 0.22 μM filter. The collection of cells on filters provides a convenient method to store and extract cellular DNA and RNA for subsequent NGS applications. Viruses present in filter flow-through can be concentrated by a diversity of methods including tangential flow filtration (TFF), FeCl_3 flocculation, polyethylene glycol precipitation, ultracentrifugation and size selection spin column filtration. TFF, FeCl_3 flocculation, and PEG precipitation methods lend themselves easily to the larger volume samples, while centrifugation-based methods are typically applicable to smaller volumes. After separation from cells, viral fractions can be further purified using

CsCl or CsSO₄ buoyant density gradients, sucrose gradients, or size exclusion chromatography. Of course, each step of any purification protocol has its own limitations, biases, and sample loss that the investigator must be aware of and plan accordingly.

Next Generation Sequencing of Samples

The availability of inexpensive, efficient NGS has greatly advanced archaeal virus discovery. Preparing nucleic acid samples from environmental virus and cellular samples for NGS requires care. It is essential that nucleic acid extraction methods minimize extraction bias while maintaining nucleic acid integrity. The minimum amount of nucleic acid required for NGS is dependent on estimated viral complexity and the DNA library construction protocol that is being utilized. Library preparation for Illumina Nano Miseq platforms requires only nanograms of input DNA while single molecule based long read technologies such as PacBio and Nanopore require high quality long DNA fragments at a higher starting concentration. It is also important to estimate the sequencing read depth required to adequately characterize the viral community, which is dependent on the estimated complexity of the viral community. A general guideline is to aim for 50–100× base coverage for every type of viral genome present. In order to determine the number of reads to generate, a researcher needs to take into account the size of the viral genome (generally 30–50k for high-temperature archaeal viruses), expected number of viruses in the community (typically 50–200 virus types), length of reads (150–300 for most NGS libraries), and desired coverage of the genome (50–100× base coverage). Hot springs with simple archaeal and viral communities can generally be well characterized with 5 million Illumina reads while a more complex community will obviously require more reads to fully sequence the viral community.

Post Sequence Analysis

A diversity of post-sequencing pipelines are available and new ones are constantly being developed for analysis of the viral community structure and the assembly of viral genomes. The overall approach requires the quality assessment of primary sequence data, sequence assembly into contigs, and post-assembly analysis. There are multiple assemblers that have been designed for NGS data. MetaSPAdes and IDBA-UD are two such assemblers. MetaSPAdes is user friendly, contains extensive documentation, and has been shown to perform well on data from a wide range of environments. MetaSPAdes also has the ability to create assemblies using both long and short reads, which generally results in higher quality assemblies and allows for the resolution between closely related viruses. Utilizing previously sequenced genomes as scaffolds can facilitate the assembly of genomes and differentiation of closely related viruses from the same or different environments. Evaluation of the quality of the assemblies is either performed by the assembler or by a stand-alone program such as QUAST. Assembled circular genomes provide confidence in the completeness of viral genomes.

As metagenomic technologies improve and metagenomic assembled viral genomes (MAVs) become more common, assessing the quality and completeness of these sequences has become more important. The Minimum Information for Uncultivated Viral Genomes (MIUViG) has been introduced to standardize the type and quality of data required to publish new MAVs (adapted from similar standards for Metagenome Assembled Microbial Genomes-MAGs). A checklist of mandatory metadata includes statistics about assembly quality, number of contigs, predicted genome type and structure, tools used for assembly and analysis and source dataset type.

One of the most challenging and exciting aspects archaeal viral metagenomic studies is gene annotation since a majority of the viral sequences have little to no similarities to sequences in the reference databases. Traditional BLASTn or BLASTx analysis typically results in only 10%–20% of genes having a significant match to known genes. More sensitive analysis such as Hidden Markov Modeling (HMM) and HHpred have demonstrated the ability to identify more viral genes but can be computationally expensive. A recent analysis of genes in almost 3000 prokaryotic viruses with HMM created ~10,000 profiles of conserved viral orthologous groups (pVOGs), along with the function of the original genes when known. This is an excellent resource for identifying known and unknown viral genes.

Network analysis based on either viral DNA sequence or their encoded proteins, is a relatively new approach to analyze viral metagenomes. These methods identify homologous sequences that are then grouped into viral “clusters” which represent closely related viral genotypes. Relatively small contigs retrieved from conventional assembly pipelines can be grouped into biologically meaningful clusters. This approach overcomes some of the challenges inherent in complex environmental samples where sample heterogeneity can limit assembly platforms that were designed for high quality deep sequencing of relatively homogenous samples. Protein clustering is another approach to reduce the complexity of metagenomic datasets and identify proteins that are shared between viruses and hot springs. However, protein clustering relies on the identification of viral genes, which can be challenging to computationally automate for archaeal viruses due to their genetic diversity from other viruses and microbes. As a result, these steps frequently require labor intensive manual curation of predicted genes greatly complicating and increasing the analysis time.

One final step in characterizing archaeal viruses is the taxonomic classification of newly discovered virus. Traditionally this has relied on the establishment of a virus infected host culture and description of the viral genome and particle morphology. Due to their morphological and genetic diversity the ~100 archaeal viruses comprise 11 recognized viral families (more than all 3000 + bacteriophage represent). However, with the rise of MIUViG culture independent classification is becoming increasingly popular.

A recently described tool vContact2 takes all predicted proteins in a viral genome and creates protein clusters that can be used to classify viral genomes at the genera, family, and order level. Further advancements and streamlining of viral characterization pipelines will greatly assist in the classification of new viral types.

A difficult but important question for any novel uncultivated virus is which cell type is the host? A number of *in silico* techniques can be combined to confidently address this question. In archaeal genomes the prevalence of CRISPR/Cas systems can greatly aid in host identification. Mapping CRISPR spacer sequences to the metagenomic assembled viral genome gives high confidence of a host-virus relationship. K-mer analysis and BLAST comparison of viral and cellular proteins can lend further support to host identification. Candidate host-virus pairs can then be validated with dual-label FISH probing of cells and viruses. This technique can also provide information about numbers of infected cells *in situ* and changes over time. Development of qPCR primers can also be used to follow viral and host population dynamics over time.

As obligate cellular parasites viruses and their nucleic acid are frequently found associated with cells, and it is worth examining cellular metagenomes for viral sequences. Most cellular genomes that have been examined to date have proviral sequences or prophages integrated into their genome. In addition, many cells are infected with actively replicating viruses and the sequencing of cell associated DNA will identify these viruses as well. Programs such as VirSorter and the archaeal virus specific MARVD identify likely viral sequences in cellular metagenomes by identification of viral hallmark genes, genome characteristics and other markers of viruses. Analysis of cellular genomes from YNP hot springs has revealed that 15%–20% of reads are likely of viral origin. While *de novo* identification of reads as viral is very difficult, the comparison to a viral database generated from purified viral particles either from the same hot spring or one with similar geochemical characteristics and microbial members greatly facilitates this process. After the viral database is created and curated, reads can be recruited onto the viral contigs in order to identify which viruses are associated with which cell type, linking viruses to cells, providing information about the host range of particular viruses and their relative abundance. Single cell genomics (SCG) can also now achieve this with much improved accuracy as intracellular viruses will be sequenced along with the host genome.

The difficulty of culturing certain cell types does not preclude further characterization of the virus using culture-independent approaches. The culture-independent methods outlined above that identify the host can aid in isolating the host and virus in culture. This is particularly true if the host is related to other cultured isolates. Virion structural proteins can often be identified from metagenomic sequence data. However, the inability to do so is no longer an insurmountable hurdle to structural studies. A purified virus fraction can be subjected to SDS PAGE and MS proteomic analysis to identify the predominant viral proteins in the fraction, which are typically the major capsid proteins. These structural proteins can then be mapped back to the predicted open reading frames in the viral metagenome to identify coat protein genes and analyzed further to give insights as to viral morphology. The identified viral structural protein genes can be cloned and expressed in a heterologous protein expression system. Expressed proteins can be used for antibody generation for use in ELISA or FISH assays. Purified proteins can also be used to solve the high-resolution structure using x-ray crystallography. Cryo electron microscopy and image reconstruction of purified virus directly from the environment can be used to generate a near atomic resolution structure of the entire virion, providing valuable insights into the virion architecture and function.

Combining viral metagenomics with other “omics” based approaches has proved to be a powerful technique to link viruses to their hosts and to ask important questions about the viral replication cycles. Paired viral and cellular metagenomes are allowing researchers to compare the viral populations within cells with that of the released extra cellular viral populations. Environmental viral metagenomic studies are being combined with environmental RNA transcriptomic studies to address questions of which virus are undergoing active replication. The identification of viral gene transcripts not only confirms that a virus is active in an environment it also can provide insight into which viral genes are the most abundantly transcribed in the system. The more abundant viral genes likely encode viral proteins that are needed in multiple copies in order to form virions (e.g., structural proteins) while less abundant viral transcripts may indicate regulatory genes that help to control the viral replication cycle. This begins to address one of the major problems with viral metagenomes in that the function of most genes was not possible to elucidate. Viral metabolomics aids in the identification of lipids that are part of the envelope in many archaeal viruses, and other components of the viral particle.

The ability to synthesize full length MAV DNA *in vitro* provides a pathway to establishing culture-based host-virus systems. Synthetic biology now allows us to express MAV DNA in suspected host cells. If a candidate host can be identified and is tractable to culturing, then a synthetic clone can potentially be transformed into a potential host and replicated, or launched off a plasmid. This may or may not lead to a productive infection, but can still provide insights into virus life cycle.

What Have we Learned?

The initial viral metagenomic studies focused on the identification of novel viruses and they helped to define the viral community structure. This era of “stamp collecting” revolutionized the study of archaeal viruses by providing insight into archaeal virus diversity and the genetic diversity of the thermophilic archaeal virosphere. For example, viral metagenomic analysis of acidic hot springs from YNP revealed that archaeal viruses dominate, that most of the assembled viruses genomes belong to uncultured viruses and that many are completely new viruses, unrelated to other known archaeal, bacterial or eukaryotic viruses. One acidic YNP hot spring was found to contain 110 virus types, of which 103 were previously unknown. Viral genomes assembled through viral metagenomics provide a roadmap and tools to track, purify and characterize these unknown viruses directly from environmental samples. For example, a

Fig. 2 *Acidianus* tailed spindle virus was purified and characterized primarily through culture independent methods.

recently described virus, *Acidianus* tailed spindle virus (ATSV) was originally isolated, its virion structurally characterized and its host identified all through culture-independent methods. This characterization guided subsequent successful efforts to culture the virus and its host (Fig. 2).

Archaeal MAVs have shown that they are genetically quite diverse. Nearly 90% of the genes present have no significant similarity to other genes in the NCBI nr database, and structural proteins were only identified in ~20% of viral types. Due to this high percentage of uncharacterized proteins, techniques other than database homology are needed to assign function to many MAV proteins. Two of the most common techniques to do this in MAVs are structural determination and genetic analysis. X-ray crystallography was used to solve the structure and determine the function of the archaeal viral protein A197 in *Sulfolobus* turreted icosahedral virus 1 (STIV1). While direct DNA sequence annotation of this protein provided little insight into its function, X-ray based structural analysis was able to identify it as a glycosyltransferase. Combined genetic and biochemical analysis has provided insight into the function of many archaeal viral proteins. This includes the discovery of a novel lysis mechanism encoded by STIV1 gene C92 which was determined to produce seven-sided pyramid shaped structures on the surface of the cell prior to lysis. Genetic studies have also showed that less than half the proteins encoded by *Sulfolobus* spindle shaped virus 1 (SSV-1) are necessary for productive infections in culture.

Despite the continued discovery of novel archaeal viral genomes, the field is rapidly moving past the cataloging of archaeal viral genomes to understanding MAVs in a broader biological context. Longitudinal sampling of YNP hot springs over time by viral metagenomics combined with targeted viral qPCR and vFISH analysis has provided insights into archaeal virus-host associations. Like all predators, viruses have been shown to fluctuate in response to their host abundance and to changes in their geochemical environment.

Temporal and longitudinal sampling allow for the comparison of MAVs across time and in different hot springs with different microbial communities and geochemical conditions. While the membership of the major archaeal virus community members can remain remarkably stable over a time frame of years, the relative abundance of a given viral type may vary considerably. Phylogenetic analysis of closely related viruses from the same hot spring over time can provide insight into viral evolution. Multiple STIV MAV's were recently compared from numerous YNP hot springs, revealing three distinct homologs of the C381 structural protein. The STIV1 and STIV2 C381-like structural proteins formed two distinct phylogenetic clusters while a third C381-like protein formed a third cluster. This suggests that a third type of STIV is present in YNP hot springs. A closer examination of the C381 clades reveals a geographic split of where each clade is predominately found. The first clade was primarily found in hot springs in the YNP Nymph Lake thermal region while the second clade was more abundant in the Crater Hills region. This local adaptation is likely in part due to the different microbial communities present in hot springs in these thermal areas.

Analysis of full length and near full length MAVs from geographically isolated (i.e., YNP, USA and Kamchatka, Russia) and geochemically distinct hot springs has identified different lifestyle strategies in different populations and different environments. For example, the lysogenic SSV strains found in the Multnovsky geyser basin (Kamchatka, Russia) were closely related to each other but distinct and genetically distant from the YNP SSV strains. Comparison across sites and over time has also enabled identification of core genes that are conserved across viral lineages through time and space as well as the flexible genome that appears to provide adaptation to the local conditions. Combining this analysis with host genome CRISPR spacer content has identified different host population immune strategies and viral countermeasures as well. For example, while all SSVs have spacer matches targeting their core genes, SSVs with fewer variable genes have fewer spacer matches to these accessory genes, while longer SSVs have many spacer matches to these accessory genes, suggesting a mechanism by which SSVs may avoid multiple host CRISPR spacer matches, and thus evade host immunity.

Combining environmental single cell genomics with population-based viral metagenomics is a powerful tool to link MAVs to their cellular hosts. A recent study took advantage of a multiyear sequencing effort of the viral community in a single hot spring in YNP and leveraged that knowledge to identify viruses in 250 single cell genomes. Despite low genome coverage of these single cells, viral sequences were identified in over 60% of the cells and sequences from multiple viruses were detected in most of the

cells. This indicates that virus-cell associations are common and leads to the speculation that most cells may be infected by viruses most of the time. Not only did this study identify high levels of virus-cell associations in the hot spring, it also identified viral hosts and host ranges for numerous viral types, and identified which viruses were actively infecting cells. While other single cell genome studies have identified viral sequences within cells they have lacked the thorough knowledge of the viral community that allowed the increased sensitivity of this study.

Looking Forward

Culture-independent approaches to investigating viruses directly in the environment are a valuable complement to traditional culture-based viral studies. This is especially true for studies of archaeal viruses from hot spring environments where there is a lack of suitable culturing systems. Viral metagenomics is rapidly progressing beyond being only a tool to describe archaeal viral diversity to a valued roadmap to address a wider range of questions. Among these questions are what viruses are infecting what cells and what is the host range of these viruses? How many cells are infected with which viruses and by how many viruses at any given moment? Overall, addressing these questions should provide insights into the bigger question of the role of viruses in driving microbial ecology and evolution in natural systems. There is still a role for the application of viral metagenomes to understand archaeal viral diversity, especially in unexplored natural environments, or in environments that contain archaeal phylum for which no viruses have yet to be discovered. However, there is an important need to leverage viral metagenomic datasets to enhance efforts to culture previously uncultured archaea and their viruses. Culture-based techniques will likely remain the gold standard to investigate details of viral processes for the foreseeable future. However, viral metagenomics are rapidly becoming initial experiments that allow researchers to refine their hypothesis and investigate biological processes in more depth.

As new sequencing technologies advance, impacts on archaeal virus discovery and characterization will further expand. The MinION sequencing platform is already allowing researchers to perform sequencing in the field. Concurrent with the improvement of current and development of new sequencing technologies is an ongoing need to generate bioinformatic tool kits and pipelines to process the large amounts of data that will be generated by these technologies. A major challenge is the development of rapid methodologies to annotate archaeal viral genes. This will likely require the combination of computational, genetic, biochemical and structural tools. The use of viral FISH and FACS tools directly on environmental samples will allow for the rapid quantification and isolation of infected cells, while the application of cryo electron microscopy techniques directly to environmental samples will provide new insights in archaeal virus structure, viral attachment and entry, replication and release from into cells.

It is likely that examining host-virus associations in their natural environments will further expand in the years to come. It is clear that many aspects of host-virus associations are evident only in the context of their natural environments and are lost when individual viruses and hosts are studied in the isolation of pure culture systems. This is particularly true when examining the ecological consequences of host-virus associations in terms of virus-virus, host-virus, and host-host competition. The interacting roles of host defense systems along with mechanisms to overcome host resistance are often only evident within the natural context of the environment. The field of environmental virology will continue to expand, embracing a much broader role of viruses in the environment from pathogens to commensal agents.

Single cell genomics and single cell transcriptomics will further our understanding of biochemistry and cell biology of archaeal virus infection. Currently single cell genomics is capable of identifying the presence of viruses in cells, but the details of viral replication are usually limited. Prokaryotic single cell transcriptomics is still in its infancy but the further advancement of the ability to sequence all of the RNA within a cell will prove crucial to identifying replicating viruses in natural environments. At the same time these techniques will provide unprecedented insight into how cells are defending against viral infection.

The field of high-temperature archaeal virology has made tremendous strides over the past two decades characterizing the morphological and genetic diversity of archaeal viruses, identifying virus-host pairs, surveying a wide range of thermal environments, and developing culture-independent techniques for viral characterization. However, the more we learn, the more we realize how much there is still left to discover. Future advances in archaeal virology over the next decade will likely require the isolation and in-depth characterization of many of these viruses and their hosts. A few of the areas that are current focuses of active research are the structural analysis, temporal fluctuations of viruses over time and the role archaeal viruses play in shaping microbial communities in natural environments.

Nomenclature

GC Guanine + cytosine content in the DNA

TEM Transmission electron microscopy

VLP Virus-like particle

Glossary

Fosmid Cloning vector that allows the cloning of large fragments (between 30 and 40 Kb) and thus can be used for cloning complete viral genomes directly purified from environmental samples.

NGS (next generation sequencing) Massive parallel sequencing technologies that allow the sequencing of a mixture of DNA molecules without the need of previously separating them by cloning.

Introduction

An environment is considered hypersaline when its salt concentration is more than twice that of seawater. This type of systems includes solar salterns, salt lakes, soda lakes, saline soils and deep-sea brines, among others. From an anthropocentric point of view, hypersaline systems are extreme environments, although this view has recently been challenged considering thermodynamic aspects. The organisms thriving in hypersaline systems are known as halophiles or extreme halophiles, depending on their salt requirements. These organisms are adapted to live in the presence of salt and need it for their normal functioning.

At very high salt, the microbiota of hypersaline systems is normally dominated by Archaea, although other organisms are also present. These Archaea include extremely halophilic members of the *Euryarchaea* and the recently described and still uncultured *Nanohaloarchaea*. Within the first group we can find the high GC extremely halophilic archaea, well represented in culture collections (e.g., *Halorubrum*, *Halobacterium*, *Haloferax*, etc.), in addition to the low GC square archaeon *Haloquadratum walsbyi*, very widespread in many environments worldwide. This archaeon, although culturable, is very difficult to grow on plates.

One remarkable characteristic of hypersaline systems is the high number of VLPs (virus-like particles) that they harbor. In fact, brines are the water systems with the highest concentration of viruses reported to date (up to 10^{10} VLPs/ml) and, frequently, with one of the highest virus to cell ratios (up to 300, when the normal values in aquatic systems are around 10 or below). Furthermore, TEM studies show that hypersaline environments harbor a wide diversity of VLP morphologies. In fact, lemon-shaped (or spindle) viruses are considered to infect exclusively archaea, although so far only one has been isolated. Indeed, as discussed elsewhere in this Encyclopedia, archaeal viruses are underrepresented in culture collections, and this is also the case for virus infecting extremely halophilic archaea.

If a microbial community is dominated by Archaea, then very likely the viral assemblage is dominated by archaeal viruses. Thus, the analysis of viral metagenomes from hypersaline environments dominated by Archaea can be very useful to get information about archaeal viruses. This can be especially valuable for learning about viruses infecting the *Nanohaloarchaea* or *Haloquadratum*, for which there are no cultured virus representatives since, to date, the only available isolated haloarchaeal viruses infect members of the high GC *Euryarchaea*. Furthermore, hypersaline systems are good models for studying viral assemblages since at very high salt viruses are likely the main factor controlling the prokaryotic communities.

How can Archaeal Viruses be Studied Using Viral Metagenomes?

In addition to the general characterization of the viral metagenome (discussed elsewhere in this Encyclopedia), a key point in the analysis is to determine which viral genomes from the viral metagenomes correspond to viruses infecting Archaea. This means assigning to their archaeal hosts the virus genomes (or genomic fragments) reconstructed from the viral metagenome.

This assignment can be accomplished by using different approaches. The safest one, albeit the less applicable given the limitation of databases, is to compare viral genomes reconstructed from metagenomes with viral genomes coming from cultured viruses (or *in silico* reconstructed viral genomes from previous works). This is particularly limited for the Archaea since, as mentioned above, all the archaeal haloviruses cultured so far infect the high GC members of the hyperhalophilic Euryarchaea which are only a part of the archaeal community. This, obviously, imposes a bias in the metagenomics-based viral identification. In any case, even for this group of viruses the identification may not be straightforward.

An example of how the tools which are very successful to analyze viruses from many environments fail to recognize viruses from extremely halophilic Archaea has been recently provided by the isolation and characterization of viruses from the hypersaline Lake Retba infecting *Haloferax* and *Halorubrum* (both high GC *Euryarchaea*). Only one out of the four viral genomes described was

recognized as virus with the powerful tool Virsorter, which is frequently used to identify viral genomes retrieved from metagenomic datasets. This, as pointed out by the authors of the study, calls for an improvement of virus hallmark datasets.

Another approach to assign viral genomes from a metagenomic library to their host is based on the fact that with time viruses tend to ameliorate their nucleotide composition towards that of the host. This is reflected in the fact that the GC difference between phages and their microbial hosts is normally around 4%, and have similar oligonucleotide frequency and codon usage, although there are considerable deviations to this trend. In any case, in the absence of other information, GC content and oligonucleotide frequency analysis can be used to assign viruses to their host in hypersaline systems. In fact, these systems are well suited for this approach since frequently the GC profiles of the community are bimodal, with a lower peak at around 45%–50% corresponding to the low GC *Nanohaloarchaea* and *Haloquadratum*, and a higher peak around 60%–65%. Accordingly, viral assemblages also display this bimodal profile.

Finally, in order to assign viruses to hosts, we can also explore the imprint that viral infection leaves in prokaryotic genomes, more specifically in the defense CRISPR/Cas system, CRISPR standing for “clustered regularly interspaced short palindromic repeat”. When exposed to the invaders (like viruses), cells harboring a functional CRISPR/Cas system may become specifically immunized by the acquisition of new spacers (i.e., sequences intervening between the repetitions) that derive from the viral DNA sequences. Thus, knowing the spacers present in a given prokaryotic genome, one can look for the corresponding protospacers in the genome of the infecting viruses. As discussed below, this approach has been used in hypersaline environments to “fish” for virus infecting different extremely halophilic archaea, such as *Haloquadratum walsbyi*, high GC Euryarchaea or members of the *Nanohaloarchaea*.

What Viral Metagenomes are Available From Hypersaline Environments and What are Their General Characteristics?

Fig. 1 shows the hypersaline environments for which viral assemblages have been characterized through metagenomics. There are basically two types of viral metagenomes in the figure that are obtained either by NGS, by directly sequencing environmental DNA, or by cloning the DNA in vectors (plasmids or fosmids) prior to sequencing. In both cases, viral DNA has to be extracted from the extracellular virus fraction in a way that avoids (or at least minimizes) cellular DNA contamination. The use of fosmids, although

Fig. 1 Publications on metagenome analysis of viral assemblages from hypersaline environments.

not devoid of technical difficulties, allows the cloning of complete virus genomes directly from the environments, providing then “natural” contigs which may simplify considerably the downstream analysis. Furthermore, these cloned viral genomes are, indeed, real genotypes present in the natural sample, and not artifacts derived from the assembly of metagenomic short reads coming from different viral genomes. However, the most frequently used approach currently use is the direct sequencing of viral DNA.

Furthermore, there is still another metagenomic strategy to analyze virus genomes, which consists of sequencing DNA extracted from the complete community, including cells and the viruses attached or replicating inside of them. In this type of metagenomes, viral sequences can only be retrieved when they have some type of similarity with previously described viruses. However, the approach can still yield valuable results like, in the case of the Atacama salt crust (see Fig. 1), the identification of a virus tentatively infecting members of the Nanohaloarchaea.

Although there is not complete agreement among all the works published so far, the comparisons of data from Senegal, Spain, United States and Australia indicate that halophilic viral metagenomes share some common traits worldwide. Thus, in the same way that there is a marine-ness in marine viruses, there is a kind of hypersaline-ness nature in viral metagenomes from hypersaline systems, with genes that are never found in other systems. Furthermore, some related lineages have been found to have a worldwide distribution. However, there is also a considerable degree of specifically local genotypes, which seem to be more important for peculiar environments such as the chaotropic Salar de Uyuni, in Bolivia, which harbors viral communities very different from what was previously known. In any case, salinity is a very strong structuring factor for viral assemblages, as previously found also for their microbial counterparts. In addition, as a rule, the higher the salinity, the higher the contribution of archaeal viruses to the total community. Furthermore, there is a temporal variation of the analyzed hypersaline systems, which can complicate the obtention of general conclusions. Finally, as frequently found in other viral metagenomes, haloarchaeal metaviromes harbor a considerably high level of diversity, as indicated by the low number of genes with matches in databases. However, as in most viruses, haloviral genomes also carry what is known as “accessory metabolic genes” which have been acquired from previous hosts. To this regard, it is specially worth mentioning the detection of rhodopsin coding genes in some uncultured halovirus. The question remains open, however, if this light driven ion pumps play any role in the infection process.

Very frequently, genomes from metagenomes of hypersaline environments correspond to viruses from the Caudovirales (head and tail viruses), that can be identified based on the presence of hallmark genes like the terminases (which are very well represented in the available databases). However, these morphologies are not always dominant in all hypersaline environments, which frequently harbor a high number of lemon-shaped viruses. These are more difficult to identify based only on genomic traits given the low number of cultured representatives to compare with. However, even with these limitation, viral genomes from metagenomes have been assigned to the lemon shaped salterproviruses in samples from Namibia, Senegal, and Australia hypersaline systems.

Although they have to be taken with caution given the limitations of the approach, several studies indicate that very likely most haloarchaeal viruses do not undergo lysogenic cycles in nature, given the low proportion of integrases detected in the analyzed metaviromes. However, to which extent haloarchaeal viruses undergo chronic infection, which is typical of some archaeal viruses, is still an open question that metagenomics has not been able to answer.

Viral metagenomics has also been used to address the dynamics of viral communities, indicating that although stable at the time scale of days, they differ significantly at larger time scales.

In the following sections we will focus on the two groups of haloarchaea from which there are no cultures viruses and thus all our knowledge comes from metagenomic studies.

Viruses of *Haloquadratum Walsbyi*

So far, we have not been able to isolate viruses infecting the square archaeon *Haloquadratum* spp., although the study of plasmid and fosmid libraries has enabled the first insight into this group of viruses as described below. In addition, a metatranscriptomic study carried out with samples from a solar saltern in Santa Pola, Spain, indicated that this part of the viral assemblage was not especially active under natural conditions but increased its activity when the community was submitted to stress.

The “environmental halophage 1”, retrieved in 2007 from a fosmid library constructed with viral DNA from the CR30 crystallizer of “Bras del Port” salterns (Santa Pola, Spain), was the first nearly complete haloviral genome that was tentatively associated to *Haloquadratum* based on its low GC content (51.4%, slightly higher than the GC content of the square archaeon, around 48%). Although this nomenclature was kept for all the viral genomes cloned in fosmid libraries, the name is not correct since the term “phage” may not be appropriate to refer to archaeal viruses.

Soon later, a second fosmid library and a plasmid library were obtained. Assembly of the plasmid library produced “uncultured viral contigs” that were grouped in different clusters together with the genomes of some extremely halophilic prokaryotes, according to their GC contents and their dinucleotide frequencies. Cluster 4, including 25% of the contigs and associated to the genome of *Hqr. walsbyi*, was interpreted to contain viruses infecting low GC haloarchaea (only represented by *Haloquadratum* at that time since nanohaloarchaea had not been described yet, but with a fraction of sequences which could, indeed, correspond to nanohaloarchaeal viruses). A third fosmid library from the same crystallizer was published in 2012, reporting a group of 14 viral genomes (also named “environmental halophages”, eHPs) which were associated to *Haloquadratum* based on genetic features. These eHPs were also reported as “very abundant” in hypersaline systems by recruitment of metagenomic reads; indeed, eHPs can recruit up to 20% of the total nucleotides from a CR30 metavirome.

Fig. 2 Some representatives of the EHqrv group I. Six fosmid-derived sequences are represented by five “environmental halophages” (eHPs) and sequence 3A2, from a 2011 fosmid library (unpublished results). Contigs 001, 004 and 005 derive from the assembly of a previous viral metagenomic library cloned in plasmids. The blue color intensity is associated to BLASTN identity percentages. Reproduced from Garcia-Heredia, I., Martin-Cuadrado, A.B., Mojica, F.J., *et al.*, 2012. Reconstructing viral genomes from the environment using fosmid clones: The case of haloviruses. PLoS One 7, e33802.

Many of these sequences, obtained from crytallizer CR30 between May 2007 and November 2014, might be joined in a new group of “*Environmental Haloquadratum Viruses*”, or EHqrv (Fig. 2). EHqrv most likely includes a (micro)diverse population of *Haloquadratum* viruses *sensu stricto*, given the high degree of genetic relatedness among them and their host: an average low GC content, a similar codon usage, very close di/tetra-nucleotide frequencies, and up to 30 proto-spacers that match the three CRISPR systems of *Hqr. walsbyi* C23^T. Also, EHqrv sequences are characterized by a remarkable degree of synteny and share some conserved genes, such as virion structural proteins and the terminase large subunit (TerL), the genetic signature to place EHqrv within the order *Caudovirales*.

Viruses of the Nanohaloarchaea

Until 2012, all extremely halophilic archaea were included within the phylum Euryarchaeota. However, that year a new group of unusually small extremely halophilic Archaea was discovered in Australian solar salterns. This group turned out to be very widespread and rather abundant in hypersaline systems worldwide. It was later named as Nanohalorcheaota and included within the archaeal superphylum DPANN, formed by phyla belonging to the so-called “microbial dark matter”, since no culture representatives are available so far. Soon after, metagenomic analyses allowed the tentative assignment of new haloviruses to this newly discovered host.

The analysis of the fosmid libraries described above also allowed the description of a group of viruses tentatively assigned to the Nanohaloarchaea. This group would also belong to the Caudovirales, given the presence of the hallmark gene terminase, unless a more surprising explanation is waiting to be discovered. In addition to the *in silico* assignment of viruses to their nanohaloarchaea host discussed above for the Atacama samples, tetranucleotide frequency and codon usage, together with CRISPR spacer analysis and the comparison with the above mentioned fosmid libraries, allowed the detection of nanohalorachaeal assembled virus genomes also in salterns of Australia and Senegal.

Although extremely powerful, virus-host assignment based solely on metagenomics remain hypothetical until experimentally proven. A combination of viral metagenomics, single cell genomics and microarrays has allowed the unambiguous characterization of a virus infecting a nanohalorachaeon host. This virus (NHV-1) turned out to be closely related to one of the nanohaloarchaeal viruses retrieved from the fosmid libraries. NHV-1 harbored a terminase (in good agreement with previous results from tentative nanohaloviruses) and as well as a putative arsenical resistance repressor-like gene, which is very widespread in cellular and viral metagenomes from hypersaline environments worldwide.

Concluding Remarks

Metagenomics has been an extremely powerful tool to unveil the diversity of the haloarchaeal virosphere, although some questions remain still open. We anticipate that the use of long read sequencing technologies and new tools of viral metaproteomics will certainly help to solve them.

Glossary

Antagonism Symbiosis in which one partner benefits.

Chronic virus A virus that buds from the host cell and does not kill its host in horizontal transmission. Chronic viruses may also persist in host cells in integrated or episomal (not integrated) forms for vertical transmission.

CRISPR-Cas immunity Adaptive immune system found in bacteria and archaea that allows for sequence-specific targeting of foreign DNA elements to prevent infection.

Horizontal transmission Movement of a viral particle from an infected host through lysis or budding that leads to adsorption of the viral particle in a new, uninfected host.

Lytic virus A virus that lyses (kills) its host as it is transmitted to the next generation.

Metapopulation Spatially separated populations connected by migration.

Mutualism Symbiosis in which both partners benefit.

Symbiosis A close interaction between two biological entities.

Temperate virus A virus that can either integrate into the host chromosome as a latent lysogen for vertical transmission or kill its host through lysis for horizontal transmission.

Vertical transmission Movement of a virus from a mother cell to a daughter cell through genome replication.

Viral fitness A measure of the number of viral progeny that are able to successfully infect host cells.

Most studies of microbial viruses in ecology and evolution focus on antagonistic lytic viruses whose transmission requires cell lysis and death. However, not all viruses are lytic. Latent proviruses are found in genomes of all cellular forms of life and persistent chronic viruses are common in all three domains. Chronic and temperate lifestyles include parts of their life cycle that are associated with their hosts. These vertically transmitted genetic units rapidly confer new evolutionary traits to their hosts and change their eco-evolutionary interactions with other organisms. Such viral symbioses result in emergent properties arising from the merging of genetic units in a process called infection genomics that links ecological and evolutionary processes and timelines. Here we expand the view of viruses to include properties across the continuum of symbiosis from antagonist to mutualists.

Aspects of Viral Fitness

To expand our understanding of archaeal viruses and their symbiosis, we first consider the virus point of view. Like all evolving genetic units, evolution will select for increased viral fitness, the number of successful progeny transmitted to the next generation (Maynard-Smith, 1989; Hartl, 1988). Viruses are transmitted to the next generation either vertically, by replicating with their host, or horizontally, by successfully establishing a new infection in a new uninfected host. Selection will act on traits (antagonistic or mutualistic) that increase viral fitness (Bull *et al.*, 1991).

Most well-known archaeal viruses are lytic and kill their host when they are horizontally transmitted to the next generation. Well-studied examples in archaea include the viruses *Sulfolobus islandicus* rod-shaped virus (SIRV), *Thermoproteus tenax* virus 1 (TTV1), and most head-tail morphology viruses that have been shown to infect methanogens and halophiles (Prangishvili *et al.*, 2006, 2017; Luk *et al.*, 2014). In conditions where horizontal transmission results in higher viral fitness, selection may act to increase fitness, for example, by increasing the number of particles produced at lysis, decreasing the time to lysis, or increasing the infectivity of the particles. It is likely that increased fitness of the virus *decreases* host fitness. This is defined as antagonism on the symbiosis continuum (Bull *et al.*, 1991; Bull, 1994; Cressler *et al.*, 2016).

Evolutionary theory predicts that horizontal fitness increases when susceptible hosts in which viruses can establish new infections are abundant. Therefore, a naive population of susceptible hosts where resistance, immunity and infection are low, and the abundance of susceptible hosts is high, should favor viral antagonism for lytic viruses. In contrast, when susceptible hosts are rare fitness is not increased by horizontal transmission (there are no new hosts) and instead vertical transmission increases viral fitness (Turner *et al.*, 1998). In this case, horizontal transmission through lysis would be selected against and viruses would evolve to become less virulent (favoring, for example, delayed lysis) (Kerr *et al.*, 2006).

Just as ecological abundance of susceptible hosts impacts the evolution of virus-host interactions, these interactions also impact the ecology of host organisms in mixed communities. For example, lytic viruses impact the abundance of their specific hosts, disrupting the stability of complex microbial communities. Lytic viruses are often modeled as having Lotka-Volterra predator-prey dynamics, causing periodic oscillations of high and low abundance for the host and virus. This impacts competition and interactions between populations of microbes and others in community of viruses and hosts in which they exist in nature (Maslov and Sneppen, 2017). Selection for host resistance to lytic viruses can promote diversification among hosts evolving as resistance or resource specialists in an eco-evolutionary dynamic known as kill the winner (Thingstad, 2000; Weitz *et al.*, 2005).

In contrast to lytic viruses, some viruses of archaea are temperate, which have a lifecycle with two distinct modes of transmission. In the lytic mode, viruses will infect the host, rapidly replicate, and kill the host through cell lysis to be transmitted horizontally; however, there is also a lysogenic or latent phase in which the virus is integrated into the host chromosome and passed vertically from mother to daughter cell through host replication (Stewart and Levin, 1984). *Sulfolobus* turreted icosahedral virus (STITV) exhibits this lifestyle when infecting its host *Sulfolobus acidocaldarius*. While it has been shown to cause a lytic infection, natural *S. acidocaldarius* isolates from Yellowstone National Park have also been found with this virus integrated in the genome (Fu and Johnson, 2012; Brumfield *et al.*, 2009; Anderson *et al.*, 2017). In halophile *Natrinema* sp. J7–1, the sphaerolipoviruses SNJ1 and SNJ2 have also shown a temperate lifestyle; however instead of integrating into the host chromosome the viral genome remains as an extrachromosomal plasmid (Liu *et al.*, 2015; Wang *et al.*, 2016).

For temperate viruses, conditions which favor horizontal transmission, such as a high density of susceptible hosts, would theoretically favor the lytic cycle. Like purely lytic viruses, selection would favor traits that, while increasing the fitness of the infecting temperate virus, would decrease the fitness of the host. However, if there was a low density of susceptible hosts, then the lysogenic cycle may be favored. When vertical transmission is favored the fitness of the virus is aligned with the fitness of the host - if the host is successful then the virus is as well. Therefore, traits that are more benevolent or beneficial to the host are selected for and shift the interaction toward mutualism, where both partners benefit from the interaction (Bull *et al.*, 1991).

While temperate viruses show either horizontal or vertical transmission in the lytic-lysogenic cycle, chronic viruses have mixed-mode transmission by exhibiting both vertical and horizontal transmission at the same time (Lipsitch *et al.*, 1996; Weitz *et al.*, 2019). These viruses produce new viral progeny through non-lytic mechanisms that allow for the continued growth of the infected host. Examples of chronically infected viruses in archaea include *Sulfolobus* spindle-shaped viruses (SSVs) and the pleomorphic viruses infecting haloarchaea (Luk *et al.*, 2014; Quemain *et al.*, 2016; DeWerff *et al.*, 2020). In chronic infection there must be a balance between both modes of transmission. In conditions that favor horizontal transmission, selection for higher fitness traits may decrease the efficacy of the vertical transmission component. The opposite may also occur where vertical transmission is favored; selection for higher fitness may work against efficient horizontal transmission.

While lytic viruses can cause instability within microbial populations, temperate and chronic viruses can shape the ecology of their microbial host by providing fitness advantages in the context of their community. The long-term association between virus and host means that the viral fitness, the ability to succeed to a new generation, is aligned to host fitness, the ability of the host to grow and divide (Bull *et al.*, 1991). When virus and host fitness are aligned, viral traits that improve host fitness can then increase the fitness of the virus as well resulting in a viral mutualism. One example of this can be accessory metabolic genes that can give the host a growth advantage compared to the uninfected population, giving their host a competitive advantage (Mann *et al.*, 2003; Lindell *et al.*, 2004; Anantharaman *et al.*, 2014; Obeng *et al.*, 2016). Another possibility would be utilizing an interference strategy where viral infection gives direct competitive advantage in which an infected cell is antagonistic against an uninfected cell, for example, through use of a toxin (Boynton, 2019; DeWerff, 2020; Gama *et al.*, 2013). Finally, some non-lytic viruses confer protection to their hosts against lytic virus infection through superinfection exclusion (Bondy-Denomy *et al.*, 2016; Labrie *et al.*, 2010; Quemain *et al.*, 2013). Any of these contributions to align virus and host fitness are considered mutualisms and are predicted to have an outsized effect that may stabilize microbial populations against the predations of lytic viruses.

As previously discussed, low abundance of susceptible hosts is predicted to favor vertical transmission however, this is not the only ecological factor that would favor this transmission mode. Spatially structured populations, even when composed of high densities of microbes, may nonetheless have a limited effective population size that is accessible to a virus (Berngruber *et al.*, 2015). Paired with low host migration rates, this can create conditions in which there is little availability of susceptible hosts at a local scale even if the broader population is susceptible. With chronic viruses, vertical transmission would theoretically be favored in the highly structured areas, but production of new viral particles is still important to allow for possible viral migration in the population which may explain why horizontal transmission is still observed in similar natural populations.

Below we explore how environments and specific molecular mechanisms shape the interactions between microbes and viruses found along this symbiosis continuum. To do this we will be reviewing what has been learned from the unique host and viral ecology of extreme environments by focusing on the model system of acidic hot springs and how this might impact their interactions (Fig. 1).

Fig. 1 In this review we explore how the virus, host, and environment together influence the broader ecology of the acidic hot spring system. TEM images courtesy of Elizabeth Rowland.

Fig. 2 Metapopulations of *Sulfolobus* hosts found in Yellowstone National Park. Each host spring makes up an island population of locally adapted hosts (and viruses). Migration and gene flow can occur, though at different scales based on distance. When extinction occurs recolonization can occur from within the population, like in the case of a bottleneck event, or competition from a new clonal type.

Environment Impact on Host-Virus Interaction

Extreme environments pose unique and highly structured landscapes for microbial life. One such environment is acidic hot springs, like those found in Yellowstone National Park, USA or Kamchatka, Russia where the model crenarchaea *Sulfolobus islandicus* can be found. *Sulfolobus islandicus* has been studied as a model not only for population structure but for its viruses as well (Anderson *et al.*, 2017; Whitaker *et al.*, 2003; Reno *et al.*, 2009; Bautista *et al.*, 2017; Munson-McGee *et al.*, 2018a). *Sulfolobus* species contain several adaptations that support growth in this environment: the enzyme reverse gyrase to maintain DNA structure at high temperatures, the proteinaceous surface layer that helps to maintain cell structure and osmotic stress, and an active proton pump that transports protons out of the cell to maintain intracellular pH (Zhang *et al.*, 2019; Forterre *et al.*, 1996; Gleißner *et al.*, 1997). The adaptations that allow for growth in the extreme environments also mean that there is low survival of *Sulfolobus* species outside of this environment, where at low temperatures DNA degradation limits the success of migration between hot springs (Hjort and Bernander, 1999). This low migration has led to metapopulations (subpopulations connected by limited migration) not only on a large spatial scale such as between continents, but on a local scale as well such as between hot springs (Fig. 2) (Anderson *et al.*, 2017; Whitaker *et al.*, 2003; Campbell *et al.*, 2017). Limited migration between populations can increase the overall genetic diversity and provide a potential for local adaptation between viruses and their archaeal hosts.

As discussed before this type of spatial structure would be hypothesized to favor either vertical transmission in temperate and chronic viruses or less virulent traits in lytic viruses, leading to local adaption between the virus and the host; however, in experimental studies this has not always been supported. When there is migration of the virus, even at low rates, it can provide enough genetic diversity to maintain the selection of antagonistic traits (Morgan *et al.*, 2005).

Like some other extreme environments, acidic hot springs are also dynamic with sporadic fluctuations in temperature and pH. In Yellowstone National Park, hot springs are subject to seasonal periods of snowmelt and rainfall in addition to geothermal excursions that rapidly change temperature and pH (Campbell *et al.*, 2017). This influx of cooler, pH neutral water in small hot springs can cause a flush or dilution of the host population. This instability can cause a significant selective sweep or bottleneck of the population that removes host diversity. In the hosts *Sulfolobus islandicus* and *Sulfolobus acidocaldarius*, population structure was studied through multi-locus sequence typing or whole genome sequencing respectively in hot springs from around Yellowstone. In populations from smaller hot springs, there was very limited diversity, with hosts belonging to one or two clonal types (Anderson *et al.*, 2017; Campbell *et al.*, 2017). Clonal types were highly associated with a single spring in time and place but were observed to change over time, suggesting an extinction-recolonization dynamic in some but not all springs. It is still not known whether the signatures of extinction are due to viral or environment extinction. Either way, this type of extinction-recolonization dynamic can counteract selection and local adaption and influence virus-host coevolution.

Finally, in acidic hot springs (as in other aquatic environments) the density of hosts is relatively low (Inskeep *et al.*, 2010). Low host density may select for higher vertical transmission or increased stability of the virion particle against prolonged environmental exposure. However, local areas of high density such as in biofilms are often observed in the environment. Biofilms are created when microbes attach to the surface and can be made of one or more microbial members. Microbes in a biofilm form three dimensional communities of relatively high density (Nadell *et al.*, 2016). While this can be a condition that allows for a virus to have access to a susceptible population, there are often extracellular structures that can limit the spread of a virus within the

biofilm itself (Simmons *et al.*, 2018; Chan and Abedon, 2015). While it has been shown that *Sulfolobus* species can form biofilms, it is unknown at this time if in nature they are found within biofilm structures or in the aquatic phase (Henche *et al.*, 2012a,b).

Viruses of Acidic Hot Springs

Viral metagenomic analysis has revealed a wealth of novel viral diversity in geothermal acidic hot springs. Deep sequencing of multiple time points from a single hot spring in Yellowstone resulted in 110 different viral clusters, of which only 7 clusters have representatives in a cultured system (Bolduc *et al.*, 2015). Within this large diversity of viruses, it would be expected that there also contains novel biology that has yet to be discovered. In the few characterized extremophilic viruses there has already been many unexpected discoveries. Some of these are adaptations to the environmental stressors placed on viral particles, such as *Sulfolobus islandicus* rod-shaped virus (SIRV), which contains A-form DNA in the viral particle (DiMaio *et al.*, 2015). A-form DNA is most commonly found within bacterial spores and helps to protect DNA from degradation. However, due to this low stability in the environment it is imperative for survival that viruses continue to infect a host. *Acidianus* two-tailed virus (ATV) leaves an infected cell through lysis as a lemon-shaped particle. Once it is in the extracellular environment it then goes through a maturation process that produces 2 long tails from the particle (Prangishvili, 2013; Prangishvili *et al.*, 2006). It is hypothesized that the extension of these tails helps to increase the chances of contact between the viral particle and the receptor of a new host.

In the host *Sulfolobus islandicus*, we will focus on just two viruses whose virus-host interactions can be found at the two ends of the symbiosis continuum. On the antagonism side of the symbiosis continuum is the *Sulfolobus islandicus* rod-shaped viruses (SIRVs). SIRVs are long stiff rod viruses with short tail fibers at one end (Prangishvili, 2013). These fibers attach to the pili of host cells and then travel down them to infect the host (Quemin *et al.*, 2013). SIRVs are lytic viruses and lyse the cell through the creation of proteinaceous pyramids in the cell membrane that open to release progeny viruses (Prangishvili and Quax, 2011). On the mutualism side we discuss the chronic *Sulfolobus* spindle-shaped viruses (SSV). These viruses are made up of lemon-shaped particle with tail fibers that often interact to form rosette-like structures of multiple viruses. The best characterized example, SSV1, was initially thought to follow a temperate lifecycle in which the virus can integrate into the genome in a lysogenic state and then, under UV induction, create new viral particles (Schleper *et al.*, 1992). However, further study into the egress mechanism showed that SSVs are not lytic but instead exit the cell through budding (Fig. 3) (Quemin *et al.*, 2016). The continued host growth of the during viral production, although with a fitness cost, suggests instead that these viruses are better characterized as chronic viruses (DeWerff *et al.*, 2020).

Like the host population, both SIRV and SSVs are also structured as a metapopulation. In initial studies using a single marker for viral presence it appeared that viruses are highly mobile (Snyder *et al.*, 2007); however, full genome sequences showed that in fact they are both structured like the host as metapopulations in Yellowstone National Park (Bautista *et al.*, 2017; Pauly *et al.*, 2019).

Fig. 3 Budding of the virus *Sulfolobus* spindle-shaped virus 9 from a chronically infected *Sulfolobus islandicus* strain. Chronically infected cells were visualized by transmission electron microscopy with negative staining. The ability of the virus to exit the cell through budding without killing the host allows for mixed-mode transmission with both vertical and horizontal transmission occurring at once. TEM images courtesy of Elizabeth Rowland.

Fig. 4 Model of CRISPR-Cas immunity found in *Sulfolobus islandicus*. On initial infection and spacer can be acquired and integrated into the leader end of the repeat-spacer array. This array is then transcribed and processed into CRISPR RNAs (crRNA) that will interact with the cascade complex. Upon reinfection with a virus carrying the same protospacer, the crRNA-Cascade complex will bind to the viral genome and degrade it to prevent infection. Figure adapted from Maria A. Bautista.

Complexity of Host Virus-Interactions

Archaea have many host defenses against viral infection including surface resistance, restriction modification and CRISPR-Cas immunity (Koonin *et al.*, 2017; Rowland *et al.*, 2019). The molecular mechanism of defense shapes the co-evolutionary dynamics of viruses and hosts. Surface modifications that commonly evolve in the lab, such as deletion of the genes encoding surface appendages, are not seen in natural populations, suggesting this type of resistance is rare in nature because appendages are essential to survival (Rowland *et al.*, 2019). Instead studies of natural populations in thermoacidophilic archaea suggest CRISPR-Cas immunity is the dominant mechanism of defense (Held *et al.*, 2010, 2013).

Clustered regularly interspaced short palindromic repeats (CRISPRs) are repeat-spacer arrays within the host where the spacers can be added that match a viral or other foreign DNA element, called a protospacer (Fig. 4) (Barrangou *et al.*, 2007; Marraffini and Sontheimer, 2008; Amitai and Sorek, 2016). The protospacers that confer immunity are limited only by a short protospacer associated motif (PAM), meaning in any viral genome there are thousands of possible loci that are targeted by CRISPR-Cas immunity. Repeat-spacer elements are transcribed and processed to form a complex with other CRISPR associated (Cas) genes. If the spacer sequence in the protein-RNA complexes matches a viral genome on subsequent infection the Cas machinery will degrade the viral genome to confer immunity. Viruses evade targeting through escape mutations in their protospacer loci or PAM (Amitai and Sorek, 2016).

Theory predicts that the unique biology of the CRISPR-Cas defense system promotes diversification of CRISPR-Cas immunity because every host infection can result in a different spacer addition to the CRISPR repeat spacer array resulting in distributed immunity (Fig. 5) (Childs *et al.*, 2012, 2014; van Houte *et al.*, 2016). High distributed immunity effectively creates a population in which there are few susceptible hosts for a virus, since each single escape mutation gives a virus access only to a very small subset of the population. The nested structure of CRISPR-Cas immunity leads to alternating regimes of stable host populations and epidemic viral outbreaks (Pilosof *et al.*, 2020).

Acr proteins are viral proteins that work to block key components of CRISPR function or regulation. The first identified antiCRISPR in archaea was found in SIRV (He *et al.*, 2018). This protein was found to interact with the CRISPR cascade complex, and this interaction led to the inability of the complex to cleave viral DNA targets (Peng *et al.*, 2020). Recently another Acr protein was found encoded in SIRV that does not directly target components of the CRISPR-Cas system but instead encodes a nuclease that cleaves a signaling molecule responsible for upregulating the CRISPR-Cas system during active infection (Athukoralage *et al.*, 2020). As stated previously, in a population with high distributed immunity theory would suggest that this would limit the susceptible population size and favor vertical transmission or lead to viral extinction (Chabas *et al.*, 2018; Childs *et al.*, 2014). The

Fig. 5 Model of distributed immunity in host populations against a virus with 4 potential protospacers. If a host population only contains spacers to one of them then it has low distributed immunity. In this scenario the virus would only need an escape mutation in the yellow protospacer to allow infection of the whole population. If there is a diversity of CRISPR spacer targets in the population then it will have high distributed immunity. In the figure above, if the virus evolved an escape mutation in any one of the protospacer it would only be able to infect one member of the host population.

presence of Acr proteins changes the interaction between viruses and their host by removing key elements of CRISPR-Cas immunity and leading to a much larger susceptible population than what spacer sequences would predict. This would ultimately favor horizontal transmission and traits associated with higher virulence.

Since the CRISPR-Cas array retains a small segment of the viral DNA in the order that it was infected, allows for the tracking both the history of infection over space and time (Held *et al.*, 2010, 2013; Held and Whitaker, 2009). Signatures of previous virus infection recorded in the CRISPR-Cas repeat-spacer sequences contain matches to SIRV and SSV but suggest there are many other types undiscovered viruses that can infect *Sulfolobus* species (Anderson *et al.*, 2017; Held *et al.*, 2010; Shah *et al.*, 2009).

CRISPR-Cas arrays in both Yellowstone and Kamchatkan populations of *Sulfolobus* have been shown to be highly diversified (Pauly *et al.*, 2019; Held *et al.*, 2010). In addition, analysis of the content of CRISPR spacer arrays from *Sulfolobus islandicus* suggest that there is a level of recombination between CRISPR arrays as well as shared spacers that were acquired independently (Held *et al.*, 2010). The degree of CRISPR-Cas spacer targeting of different viruses reflect the viruses and their host interactions in natural populations. *Sulfolobus islandicus* isolated from Kamchatka, Russia highly target *Sulfolobus* spindle shaped viruses (SSVs) but lack targeting to *Sulfolobus islandicus* rod-shaped viruses (SIRVs); whereas host populations from Yellowstone National Park, USA highly target SIRVs and only have low immunity to SSVs (Pauly *et al.*, 2019). This matches what has been seen with viral isolation from these locations – while SSVs are quite commonly isolated from Kamchatka hot springs, to date there has yet to be a SIRV isolated. While in Yellowstone National Park hot springs SIRVs are quite common while SSVs, though present, are not the primary viruses isolated from these location.

How do Ecology and Evolution Shape Archaeal Viruses?

Putting the pieces together, can we predict how will viruses evolve along the symbiosis continuum in natural populations of archaea in extreme environments? In the context of a metapopulation the landscape of susceptible hosts may be highly varied. One hot spring may contain a population with highly distributed CRISPR-Cas immunity, while another one nearby that has recently experienced a bottleneck or extinction may lack diversified spacers that can target the population. If viral migration occurs between hot springs or a host bottleneck occurs within a hot spring there could be a viral boom period with a large susceptible population or a bust period where no susceptible hosts are present, effectively causing viral extinction unless escape mutations are present. It is within these two different scenarios that we will explore how selection will move the virus-host interactions along the symbiosis continuum.

During a viral boom period there is a large susceptible population that can be infected by the virus. When finding a new host is no longer the selective pressure, traits that are favored are ones that will increase the chance of horizontal transmission. This can be accomplished by increasing the number or infectivity of viral progeny or decreasing the time needed for a complete infection cycle. Viruses that have a decreased infection time will have a greater chance of infecting and spreading within the susceptible population compared to their longer infection cycle counterparts. However, these traits that are selected for are tied with an increase in virulence for lytic viruses (as described above). This increase in virulence is harmful to the host population and shifts the interaction toward the extremes of antagonism. Selecting for the quick use of susceptible hosts within the population for faster spread can lead to a tragedy of the commons in which the shared resource, in this case the susceptible hosts, is depleted by the viral population, which can ultimately lead to a bust period in which there is a low or absence of susceptible hosts (Kerr *et al.*, 2006). There is highly distributed immunity among populations of *Sulfolobus islandicus* against the virus SIRV in this environment; therefore it is perhaps not surprising that there is not one, but two types of antiCRISPRs present in SIRVs as these genes would be highly selected for to increase the fitness of the virus (Peng *et al.*, 2020).

In a viral bust period in which there are few susceptible hosts, selection will favor viruses that are more prudent with their hosts. For lytic viruses, this would select for lifestyle characteristics that increase the time of infection within the host allowing for production of

Fig. 6 Virus–host interactions fall along a symbiosis continuum. When a virus decreases host fitness it moves towards antagonism in which one partner benefits at the cost of the other. If both virus and host gain benefits from the interaction, then it is shifted toward mutualism.

either high quantity or quality of new viral progeny. However, this bust period would also strongly favor viruses that are not strictly lytic but instead follow a dual- or mixed-mode transmission such as with temperate or chronic infection. During a bust period, viruses that are already vertically associated with their hosts would be protected from environmental degradation of the genome or virion particle. This would select for mutualistic traits as discussed earlier that would give a benefit to the infected host (Bull *et al.*, 1991). This has been shown recently with SSV9 infection of the archaea *Sulfolobus islandicus*. Kamchatka populations exhibit high distributed CRISPR-Cas immunity to SSVs, which limits the size of the susceptible population (Pauly *et al.*, 2019). Though chronic infection comes at a cost in cell growth, DeWerff *et al.* showed that infected cells produce a toxin that kills uninfected and immune cells. This killing of competitors gives a benefit not only to the infected host cell through toxin immunity but the chronic virus as well (DeWerff *et al.*, 2020). The virus can ensure its continued vertical transmission by the toxin acting in a similar manner to plasmid addiction systems, and selects for successful horizontal transmission by only allowing the infected cells to survive. Given the structure of these metapopulations, a competitive ability would give a substantial benefit to the host. In its established hot spring, the ability to remove uninfected cells would suggest that the chronically infected cell becomes the dominant member. If migration to a new hot spring were to occur, the chronically infected host would be able invade an established uninfected population (even one with distributed CRISPR-Cas immunity) by killing established local hosts.

How do Virus Interactions Impact Ecology and Evolution?

So far, we have considered how both viruses, the lytic SIRV and chronic SSV, interact individually with their host and shape the ecology of the system. With SIRVs the ability to prevent CRISPR-Cas function allows for a larger susceptible population despite the high targeted distributed immunity that can be seen in these populations. This allows for selection of traits that are associated with high virulence in the host and shift the interaction toward antagonism (Fig. 6). On the opposite end of the spectrum, SSVs can establish chronic infection that allows for both vertical and horizontal transmission of the virus. The chronically infected host and virus benefit from this interaction through the competitive advantage that is conferred by production of a virally-encoded toxin that kills uninfected cells. This is in line with the selection of benevolent traits predicted to be associated with vertical transmission and a shift of the symbiotic relationship toward mutualism.

However, in Yellowstone National Park, both SSV and SIRV viruses can be found simultaneously in hot springs. How does the presence of both change the eco-evolutionary dynamic of each individually? It is necessary to go beyond thinking about one virus – one host interactions and consider those when multiple types of viruses are present. Infection of a chronically infected host with a lytic virus would be detrimental not only to the host but the chronic virus infecting this host cell as well.

The metapopulation nature of acidic hot springs and extinction-recolonization dynamic suggest that competition between host strains to invade new habits and quickly establish as the dominant member is a strong driver of selection for viruses that confer competitive advantages and remain with their hosts. Studying natural isolates from these populations as well as single cell genomics has shown that while most cells are infected by at least one virus in nature, chronic infection with SSV does not dominate each subpopulation with Yellowstone National Park (Pauly *et al.*, 2019; Munson-McGee *et al.*, 2018b). Taken together, the interactions discussed here must be more complicated and further research into novel archaeal virus mechanisms is needed to fully understand their eco-evolutionary impact.

Through the lens of extreme environments, the expanding view of viruses to include positive mutualistic impacts on their hosts provides dramatic insight into ecology and evolution in the microbial world especially on contemporary time-scales. In addition, study of viral symbiosis is uncovering the diversity of molecular interactions within cells that contribute to their physiology. In this way, the dual role of viruses as individuals and as genetic elements shows us that integrating molecular mechanisms with their eco-evolutionary impacts will play an increasingly important role in biology going forward.

Acknowledgments

We thank Elizabeth Rowland for help and inspiration on the initial drafts of this manuscript and TEM images. Work included discussed here was funded by NSF DEB #1656869.

FUNGAL VIRUSES

An Introduction to Fungal Viruses[☆]

Nobuhiro Suzuki, Institute of Plant Stress and Resources (IPSR), Okayama University, Kurashiki, Japan

© 2021 Elsevier Ltd. All rights reserved.

This is an update of S.A. Ghabrial, N. Suzuki, Fungal Viruses, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy, Marc H.V. Van Regenmortel, Elsevier Ltd, 2008, doi:10.1016/B978-012374410-4.00563-X.

Glossary

Hyphal anastomosis The union of a hypha with another resulting in cytoplasmic exchange.

Hypovirulence Attenuated fungal virulence mediated by virus infection, mitochondrial defects, or mutations in the fungal genome.

Mycoviruses Viruses that infect and multiply in fungi.

Vegetative incompatibility A genetically controlled self/non-self recognition system in fungi that determines the ability to undergo hyphal anastomosis. This is regarded as antiviral defense that operates at the population level.

Virocontrol One form of biological control using viruses. Control of crops against phytopathogenic fungi utilizing viruses infecting them.

Introduction

Relative to plant virology, animal virology, or bacterial virology, fungal virology (or mycovirology) is new. In 1948, an economically important disease of the cultivated edible mushroom, *Agaricus bisporus* (a basidiomycete), characterized by malformed fruiting bodies and serious yield loss, was first reported in a mushroom house owned by the La France Brothers of Pennsylvania. The disease was called “La France disease”, and similar diseases were reported shortly thereafter from Europe, Japan, and Australia. Different designations, such as “X-disease”, “watery stripe”, “brown disease”, and “die-back” were given to basically the same disease as La France. The significance of the 1948 report lies in the fact that it led to the discovery of fungal viruses (mycoviruses). In 1962, Hollings noted the presence of at least three types of virus particles in diseased mushroom sporophores. This was the first report of virus particles in association with a fungus and is regarded as the dawn of mycovirology. The subsequent discovery that dsRNA of mycoviral origin was responsible for interferon-inducing activities of cultural filtrates of several species of *Penicillium* spp. (ascomycetes) greatly stimulated the search for mycoviruses.

Fungi, like other living organisms, can be infected by a number of viruses, and mycoviruses are found in all the major groups of fungi such as the Ascomycota and Basidiomycota as well as fungal-like protists such as Oomycota (see below). Although mycoviruses are widely prevalent, only those infecting a limited number of fungal host species have been studied, e.g., the yeast *Saccharomyces cerevisiae*, edible mushrooms and phytopathogenic fungi. Given the predicted vast number of fungal species (approximately 120,000 accepted species and much more unknown species), it is expected that a greater number of unrecognized mycoviruses occur in nature. Support for this hypothesis comes from recent extensive searches of field fungal isolates that showed relatively high frequencies of virus infection, e.g., approximately 65%, 20%, and 2%–28% of isolates of *Helicobasidium mompa* (a basidiomycete that causes violet root rot), *Rosellinia necatrix* (an ascomycetes called the white root rot fungus) and *Cryphonectria parasitica* (an ascomycetes called the chest blight fungus) were found to be infected, respectively. Another line of support is from recent next-generation sequencing and metaviromic analyzes of environmental and plant-associated samples discovering numerous viruses most likely of fungal origin.

Biological Properties

Host Range

The natural host range of mycoviruses is likely to be restricted to the same or closely related vegetative compatibility groups that allow lateral transmission. The development of inoculation or introduction methods allows testing of experimental host ranges. Until recently, there were no known experimental host ranges for fungal viruses because of a lack of suitable infectivity assays. Experimental host ranges for some mycoviruses, however, were recently demonstrated and shown to extend to different vegetative compatibility groups, different species, different genera and even to different classes. For example, mycoreovirus 1 (MyRV1, an encapsidated dsRNA virus), the prototype of the genus *Mycoreovirus* in family *Reoviridae*, can replicate and induce phenotypic alterations in different vegetative compatibility groups of *C. parasitica* similar to those exhibited by the original virus-containing strain. Furthermore, *Cryphonectria hypovirus* 1 (CHV1, a capsidless (+)ssRNA virus), the type member of the family *Hypoviridae*, can replicate in and confer hypovirulence onto members of several other ascomycete genera, e.g., *Endothia gyrosa* and *Valsa ceratosperma*, fungi associated with diseases of trees such as eucalyptus or apples and pears, in addition to its natural host, *C. parasitica*. *Cryphonectria parasitica* mitovirus 1 (CpMV1, the genus *Mitovirus*), a mitochondrially replicating capsidless (+)ssRNA virus, can be replicated in *Valsa* spp., but not in fungi more distantly related to its original host *C. parasitica*. Of particular

[☆]In memory of Professor Said A. Ghabrial.

note is the recent discovery of cross-kingdom infections by a few fungal viruses between fungi and plants or fungi and insects (see below).

Symptom Expression

Although the majority of viruses that infect phytopathogenic fungi have been reported to be avirulent, phenotypic consequences of infections with mycoviruses can vary from symptomless to severely debilitating, and from hypovirulence to hypervirulence. Mycoviruses that attenuate the virulence of plant pathogenic fungi provide excellent model systems for basic studies on development of novel biological control measures and for dissecting the mechanisms underlying fungal pathogenesis. In general, infections due to mycoviruses are both symptomless and persistent. Latency benefits the host for survival, and persistence helps the virus in the absence of extracellular modes of transmission. To ensure their retention, some mycoviruses have evolved to bestow selective advantage to their host (e.g., the “killer” phenotypes in yeasts and smuts that are associated with the totivirus infection). Because of their ability to secrete killer toxins, yeast killer strains have been utilized by the brewing industry to provide protection against contamination with adventitious sensitive strains. The genes encoding the smut killer toxins have been used for development of novel transgenic approaches to control the corn smut.

Macroscopic symptoms caused by fungal viruses are a consequence of alterations in complex physiological processes that involve interactions between host and virus factors. Several virally encoded proteins are identified as symptom determinants including the papain-like protease, p29, of some hypoviruses that are phylogenetically related to potyviruses and viruses belonging to the picorna-like superfamily. This protein acts to repress host pigmentation and conidiation regardless of whether it is expressed from host chromosomes or the homologous virus genome. A protein encoded by one of the betachrysovirus (family *Chrysoviridae*) dsRNA genomic segments acts as a symptom determinant of phytopathogenic host fungi. Another interesting example is the proteins encoded by the totivirus *Helminthosporium victoriae* 190S virus (HvV190S, the prototype of the genus *Victorivirus*) infecting the filamentous ascomycete *Helminthosporium victoriae*, the causal agent of Victoria blight of oats. Co-expression of the HvV190S capsid and RdRP proteins results in empty capsid production and phenotypic changes similar to those induced in virus-infected fungal isolates, suggesting that viral replication is not required for symptom development. Host factors involved in symptom expression are not well studied except for host genes involved in the killer phenomenon in yeast infected with the totivirus *Saccharomyces cerevisiae* virus L-A (ScV-L-A) and its associated satellite dsRNAs as exemplified by super killer genes and the symptom expression by CHV1 in *C. parasitica*. A genetic screen for host factors led to the identification of a Mg^{2+} transporter as being necessary for normal symptom induction by CHV1 in *C. parasitica*. The putative mRNA binding protein, termed virus response 1 (*vr1*), and hexagonal peroxisome protein (Hex1) of the filamentous ascomycete *Fusarium graminearum*, the causal agent of fusarium head blight, are associated with symptom expression induced by a betachrysovirus (*Fusarium graminearum* virus China 9, FgV-ch9) and a fusarivirus (*Fusarium graminearum* virus 1, FgV1, a capsidless (+)ssRNA virus related to hypoviruses), respectively. Transcriptome analysis was performed for only limited virus/natural host combinations. In the *C. parasitica*/mycovirus pathosystem, the SAGA (Spt-Ada-Gcn5 acetyltransferase) complex, a general transcriptional co-activator and DCL2 (a Dicer), a key enzyme of antiviral RNA silencing, mediate the upregulation of many host genes. Some of the virus responsive *C. parasitica* genes are associated with CHV1 symptom expression or its mitigation. Of the 2200 *C. parasitica* genes, 13.4% are either up- or down regulated upon infection with the prototype strain (a severe strain) of CHV1, while only 7.5% are altered in their transcription levels by infection with a mild strain of CHV1. Half of the *C. parasitica* genes responsive to the infection with the latter mild strain are commonly altered in transcription by the severe strain, which generally causes greater magnitude of transcriptional changes.

Transmission

Mycoviruses generally lack an extracellular phase to their life cycles. They are transmitted intracellularly during cell division, sporogenesis and cell fusion. Lateral (horizontal) transmission usually occurs only between individuals within the same fungal species, which belong to the same or closely related vegetative compatibility groups. Vegetative compatibility is governed genetically. Mycoviruses may be eliminated during sexual spore formation. Although the totiviruses and narnaviruses (capsidless (+)ssRNA viruses belonging to the family *Narnaviridae*) that infect the budding yeasts are effectively transmitted via ascospores, the mycoviruses infecting the ascomycetous filamentous fungi are in effect eliminated during ascospore formation. Whereas the (+)ssRNA and dsRNA viruses infecting mushrooms are transmitted efficiently via basidiospores, the virus-containing strains of the basidiomycete *H. mompa* are cured during the sexual sporulation processes. Therefore, whether a mycovirus is transmitted through sexual spores depends on the host/virus combination involved. Whereas mycovirus transmission through asexual spores occurs frequently, its rate varies greatly depending on the combination of viral and host fungal strains. It was recently revealed that CHV1 p29 (the papain-like protease p29) might play a role in virus transmission since it enhances the transmission of the homologous virus (CHV1) as well as a heterologous virus (a mycoreovirus, MyRV1) through the conidia in *C. parasitica*.

Though rare in nature, interspecies transmission has been reported between members within the same genus including *Cryphonectria*, *Sclerotinia*, and *Ophiostoma* that share the same habitats. Interspecies transmission is also implicated between distantly related fungi, e.g., between *R. necatrix* and *Entoleuca* spp. It remains unknown whether the interspecies barrier is overcome by physical contacts, by vectors, or by infecting viruses.

Of note is the recent discovery of extracellular routes for mycovirus entry. There is experimental evidence for the transmissibility of an encapsidated ssDNA virus, *Sclerotinia sclerotiorum* hypovirulence associated DNA virus 1 (SsHDV1, the family *Genomoviridae*), by a mycophagous fly between *Sclerotinia sclerotiorum* (an ascomycetous plant pathogen with a broad host range) colonies and the acquisition and replication of a plant (+)ssRNA virus by/in *Rhizoctonia solani* (a basidiomycetous plant pathogen that has a wide host range). See the Section “Cross-Kingdom Infection by Viruses and Viroids” in this article.

Mixed Infections

Mixed infections with two or more related or unrelated viruses and accumulation of defective dsRNA and/or satellite dsRNA molecules are common features of mycovirus infections. Examples include the totiviruses (Sphaeropsis sapinea RNA virus 1 and 2, genus *Victrivirus*) infecting *Sphaeropsis sapinea* (an important opportunistic fungal pathogen on pine trees) and *S. cerevisiae* (ScV-L-A and ScV-LB/C), and *Penicillium stoloniferum* gammapartitiviruses (*Penicillium stoloniferum* virus S and F). There are a number of known examples of mixed infections with plant or animal viruses where one virus either interferes with or enhances the replication of the other one. As a consequence, reduction or increase in symptom severity may arise.

Recent extensive searches for fungal viruses confirmed relatively high mixed infection rates in some phytopathogenic fungi like *C. parasitica*, *R. necatrix*, *Heterobasidion* spp. (a root rot basidiomycete fungus), *S. sclerotiorum* and *H. mompa*. There are at least three types of recognizable virus/virus interactions: synergistic, mutualistic and antagonistic interactions and genome alterations.

Recent studies show synergistic interactions between a hypovirus (CHV1) and a mycoreovirus (MyRV1) through a hypovirally-encoded protein. In this case, one-way synergism is observed in that only the hypovirus infection trans-activates the replication of the mycoreovirus, which has a replication strategy distinct from that of hypoviruses. A similar one-way synergistic interaction is detected between *Cryphonectria hypovirus* 4 (CHV4) and mycoreovirus 2 (MyRV2), in which CHV4 enhances stable infection and replication of MyRV2 in *C. parasitica*. These two examples of synergism are mediated by papain-like cysteine proteases p29 and p24 encoded by CHV1 and CHV4, respectively, both of which also play a role in the suppressor of antiviral RNA silencing. Genome rearrangement occurs in *C. parasitica* co-infected with MyRV1 and CHV1 which is a result of RNA silencing suppression via the action of the CHV1 p29. Synergistic interactions are also found between a megabirnavirus, *Rosellinia necatrix* megabirnavirus 2 (RnMBV2, an encapsidated dsRNA virus, the prototype of the genus *Megabirnavirus* in family *Megabirnaviridae*) and a partitivirus, *Rosellinia necatrix* partitivirus 1 (RnPV1), in which RnMBV2 confers hypovirulence with the aid of RnPV1 and elevates the accumulation of RnPV1. For antagonistic and mutualistic interactions, see the “Future Perspectives” Sections below.

Fungal Virus Taxonomy

A list of the virus families and genera into which mycoviruses are classified or officially proposed to the international committee on taxonomy of viruses (ICTV) is included in [Table 1](#). Mycoviruses have diverse genomes including ones made of linear dsRNA, linear positive-sense (+) ssRNA, linear negative-sense (−) ssRNA, and circular ssDNA.

Mycoviruses with dsDNA genomes are not in the list, but might yet be found since dsDNA viruses of water molds, now classified as protists not fungi, have been reported. Mycoviruses for which three-dimensional (3D) structures of the virions have been reported are further described in “Structural features”.

Members of some mycovirus families, e.g., the families *Narnaviridae*, and *Hypoviridae*, infect only fungi, while members in other families, e.g., the families *Metaviridae*, *Pseudoviridae*, *Reoviridae*, *Totiviridae*, *Chrysoviridae*, *Endornaviridae*, *Alphaflexiviridae*, *Botourmiaviridae* and *Partitiviridae* infect fungi, protozoa, plants or animals.

Many mycoviruses have RNA genomes and have either dsRNA genomes or (+)ssRNA genomes. Viruses with (−)ssRNA (monopartite mymonaviruses and multipartite phenuiviruses) or circular ssDNA genomes have recently been reported. Since the article of the last edition of this series was published, an extremely large number of viruses have been identified.

Visit See “Relevant Website section” for an updated list of all mycoviruses. Note that there are still many unassigned mycoviruses awaiting official taxonomical classification. [Table 1](#) represents these mycoviruses in the “unassigned” sections.

dsRNA Mycoviruses

Mycoviruses with dsRNA genomes represent a major portion of the fungal-infecting viruses so far reported. With the exception of the mycoviruses (family *Reoviridae*), which have spherical double-shelled particles 80 nm in diameter, the typical dsRNA mycoviruses are isometric particles ranging 25–50 nm in diameter. In addition, for polymycoviruses (family *Polymycoviridae*) with multipartite dsRNA genomes, two viral forms, a filamentous encapsidated and a capsid-less RNA-protein complex forms, have been proposed. These dsRNA viruses are classified, based on the number of genome segments and phylogenetic relation, into one genus *Botybirnavirus* and eight families, *Totiviridae*, *Partitiviridae*, *Curvulaviridae*, *Amalgaviridae*, *Chrysoviridae*, *Megabirnaviridae*, *Quadriviridae*, and *Polymycoviridae* ([Table 1](#)).

Viruses in the family *Totiviridae* have non-segmented dsRNA genomes coding for a CP and an RdRP or CP-RdRP fusion protein. At present, five genera have been placed in this family: *Totivirus*, *Victorivirus*, *Giardiavirus*, *Leishmanivirus*, and *Trichomonasvirus*.

*The type species of the specified genus is underlined.

^bProposed taxa for new creation or re-classification (awaiting EC consideration and ICTV 2020 ratification) are asterisked.

Viruses in the genera *Totivirus* and *Victorivirus* infect fungi, whereas those belonging to the latter three genera infect parasitic protozoa. Plant-infecting dsRNA viruses related to totiviruses (potential members of genus *Totivirus*) were recently found. At least two distinct RdRP expression strategies have been reported for totiviruses: (1) those that express their RdRP as a fusion protein (CP-RdRP or Gag-Pol) by ribosomal frameshifting, such as the yeast ScV-L-A and the viruses that infect parasitic protozoa and (2) those that synthesize RdRP as a separate non-fused protein by an internal initiation mechanism (e.g., a coupled termination–reinitiation mechanism), as demonstrated for HvV190S (a victorivirus) and others that infect filamentous fungi. Phylogenetic analysis of CP or RdRP sequences of totiviruses reflects these differences, and separate phylogenetic clusters can be generated. HvV190S and other victoriviruses that infect filamentous fungi are closer to each other than to viruses infecting yeast, smut fungi and protozoa. The fact that independent alignments of CP and RdRP sequences give similar phylogenetic relationships supports the conclusion that totiviruses infecting filamentous fungi should reside in a genus of their own. HvV190S and other known totiviruses that infect filamentous fungi have been classified within

the genus *Victorivirus* (Table 1). The genomes of partitiviruses, curvulaviruses, and megabimaviruses consist of two dsRNA segments, while chrysovirus, quadriviruses, and polymycoviruses have three to seven, four, and four to seven dsRNA segments, respectively.

The unclassified dsRNA mycovirus *Agaricus bisporus* virus 1 (AbV1), also designated La France isometric virus, causes a serious disease (named La France disease) of the cultivated mushroom *Agaricus bisporus* (white button mushroom). AbV1 is of special interest because of its historical and economic importance. The AbV1 virions, isolated from diseased fruit bodies and mycelia, are isometric 36 nm in diameter and co-purify with nine dsRNA segments (referred to as disease-associated dsRNAs). The size of dsRNA segments varies from 3.6 kbp to 0.78 kbp, three of which are believed to be satellites. It is not clear at present whether the nine dsRNA segments are encapsidated individually, in various combinations, or all segments are packaged in single particles. Based on the size of the particles, cesium sulfate gradient profile and results of dsRNA and protein analyses of the gradient fractions, it is highly unlikely that all dsRNAs are packaged together in single particles. More realistically, AbV1 represents a multiparticle system in which the various particle classes have similar densities. Interestingly, phylogenetic analysis of the conserved motifs of AbV1 RdRP, encoded by dsRNA segment 1, and other dsRNA mycoviruses showed that AbV1 is closely related to the multipartite chrysovirus. The Blast analyses also supported the above notion.

In addition to AbV1, there are an increasing number of unclassified dsRNA mycoviruses. Table 1 lists only some of those well-characterized.

Single-Stranded RNA Viruses

Single-stranded (ss) RNA mycoviruses are grouped into two with linear positive-sense (+)ssRNA genomes (currently classified into nine families: *Alphaflexiviridae*, *Barnaviridae*, *Deltaflexiviridae*, *Endornaviridae*, *Gammaflexiviridae*, *Hypoviridae*, *Narnaviridae*, *Mitoviridae*, and *Botourmiaviridae*) and with linear (–)ssRNA (family *Mymonaviridae*, and *Phenuiviridae*) (Table 1). Among them are mycoviruses with apparent ssRNA genomes that do not code for capsid proteins and exist more or less predominantly as dsRNA “replicative” forms in their hosts. Because of the lack of true virions, these viruses were easier to isolate and study as their replicative dsRNA forms, and some were grouped with dsRNA viruses (e.g., family *Hypoviridae*). However, there is ample evidence that many of these mycoviruses replicate and express their genomes like (+)ssRNA viruses and that the lineage of their RdRP and helicase genes are within the lineages of (+)ssRNA viruses. The simplest types of these viruses include members of the families *Narnaviridae* and *Mitoviridae*, whose RNA genomes code only for RdRP and the viruses exist as RNA/RdRP ribonucleoprotein (RNP) complexes. The corresponding dsRNA replicative forms can be isolated from infected tissues, usually in smaller molar amounts than the genomic ssRNA. Phylogenetic analysis of RdRPs of members of the families *Narnaviridae* along with those of other mycoviruses and related taxa indicate a distant relationship between members of the family *Narnaviridae* and bacteriophages such as Q β and MS2 belonging to the family *Leviviridae*. Viruses in the family *Botourmiaviridae* are phylogenetically more closely related to narnaviruses than to mitoviruses. The family accommodates four genera: *Ourmiavirus*, *Botoulivirus*, *Magoulivirus*, and *Scleroulivirus* together with two newly proposed genera “*Penoulivirus*” and “*Rhizoulivirus*.” Viruses belonging to the first genus infect plants associated with host diseases and have tri-partite (+)ssRNA genomes, whereas viruses in the other genera infect filamentous fungi, and have mono-partite (+)ssRNA genomes encoding only RdRPs. These fungal viruses are capsidless, and likely are replicated in the cytoplasm.

Lack of true virions (a capsid-less nature) is characteristic of two other groups of classified (+)ssRNA viruses, those belonging to the family *Hypoviridae* and the family *Endornaviridae*. Viruses in the family *Hypoviridae* are phylogenetically related to the (+)ssRNA viruses in the family *Potyviridae* (picorna-like virus supergroup). Comparisons of hypovirus conserved motifs of RdRP, helicase and protease with those of members of the family *Potyviridae* suggest that viruses in the genus *Bymovirus*, which are plant viruses transmitted by soil-borne plasmodiophorid *Polymyxa graminis*, are the closest relatives to hypoviruses. Fungal endornaviruses belong to the genus *Betaendornavirus*. Exceptionally, a few non-plant viruses in the genus *Alphaendornavirus*, such as *Phytophthora endornavirus* 1 and *Rhizoctonia cerealis endornavirus* 1, infect fungi and oomycetes. Most other *alphaendornaviruses* infect plants. Although *Phytophthora* species and other members of the family *Pythiaceae* (Oomycetes) have many biological properties in common with fungi, they are currently classified, based on sequence similarities, in a protist group known as the Stramenopiles. Endornaviruses are believed to have evolved from an alpha-like virus that has lost its capsid gene. This is consistent with the recent finding that RdRPs of PEV1 and other endornaviruses cluster with those of families and genera in the alpha-like virus superfamily of (+)ssRNA viruses.

The mushroom bacilliform virus (MBV; genus *Barnavirus*, family *Barnaviridae*) is the only mycovirus known to have bacilliform virions. MBV has a (+)ssRNA genome that contains seven ORFs, three of which encode a putative chymotrypsin-like serine protease, a putative RdRP and a CP. The polypeptides encoded by the remaining four ORFs have no homology to known proteins. Amino acid sequence comparisons of the putative protease and RdRP suggest that MBV is evolutionarily related to sobemoviruses and poleroviruses, both of which have smaller monopartite (+)ssRNA genomes and spherical particles. Although double infections of cultivated mushrooms with MBV and ABV1 occur commonly, the role of MBV in the ensuing dieback disease of cultivated mushroom remains unknown.

Botrytis virus F (BVF) has flexuous rod-shaped particles comparable in size and morphology to (+)ssRNA plant flexiviruses such as potato virus X (a potexvirus, family *Alphaflexiviridae*). Amino acid sequence identities of the conserved helicase and RdRP regions and the CP genes are most similar to those of potex-like viruses. The main difference between BVF and these plant viruses is the lack of a movement protein (MP) gene(s), which encodes a key protein(s) in cell-to-cell movement of a plant virus. Despite

similar particle morphology along with amino acid sequence similarities of both the replicase and CP genes, it is obvious that the mycovirus BVF is distinct enough to belong to a new family. It has been approved by ICTV as an exclusive genus and family designated as *Mycoflexivirus* and *Gammaflexiviridae* that were created to include BVF (Table 1).

The genome of *Sclerotinia sclerotiorum* debilitation-associated RNA virus (SsDRV) contains a single ORF encoding a protein with significant sequence similarity to the replicases of the “alphavirus-like” supergroup of (+)ssRNA viruses. The putative SsDRV-encoded replicase protein contains the conserved methyl transferase, helicase and RdRP domains characteristic of the replicases of plant alphaflexiviruses (family *Alphaflexiviridae*) and BVF. Although phylogenetic analysis of the conserved RdRP motifs verified that SsDRV is closely related to BVF and to the allelerviruses in the family *Alphaflexiviridae*, SsDRV is distinct enough from these viruses, mainly based on the lack of CP and MP genes, to justify the creation of another genus, *Sclerodarnavirus* in the family *Alphaflexiviridae*. Another mycovirus member of the genus *Sclerodarnavirus* is *Botrytis virus X* (BVX) (Table 1). Recent taxonomical reorganization of related viruses includes the creation of the genus *Deltaflexivirus*, family *Deltaflexiviridae* that accommodates three mycovirus members such as *Sclerotinia sclerotiorum* deltaflexivirus 1 and *Fusarium graminearum* deltaflexivirus 1.

A negative-sense (–)ssRNA virus termed *Sclerotinia sclerotiorum* negative-stranded RNA virus 1 (SsNSRV1) was isolated in 2014. SsNSRV1 is now classified in the species *Sclerotinia sclerotimonavirus*, genus *Sclerotimonavirus* (family *Myonnaviridae*, order *Mononegavirales*). SsNSRV1 forms filamentous nucleocapsid structures of 22 nm × 200–2000 nm and appears to employ a gene expression strategy with sequential transcription (“stop-start”) mechanism similar to other mononegaviruses. The family accommodates one genus *Sclerotimonavirus* and other newly proposed or renamed genera “*Botrytimonavirus*,” “*Lentimonavirus*,” “*Phyllomonavirus*,” “*Auricularimonavirus*,” “*Penicillimonavirus*,” and “*Plasmopamonavirus*.” Multipartite (–)ssRNA viruses have also been reported from edible shiitake mushroom (*Lentinula edodes* negative-strand RNA virus 2) and *Entoleuca* sp. infecting avocado (*Entoleuca bunyavirus* 1). Both viruses have a smaller segment with the putative ambisense coding strategy.

Unassigned ssRNA Viruses

It is worth noting that a relatively large number of mycoviruses remain unassigned including some well-characterized ones like *Diaporthe* RNA virus (DRV), and *Sclerophthora macrospora* viruses A and B (SmV-A and SmV-B) (Table 1). DRV is another naked RNA mycovirus that is associated with hypovirulence of its fungal host. It has two large ORFs present in the same reading frame, which are most likely translated by readthrough of an UAG stop codon in the central part of the genome. The longest possible translation product has a predicted molecular mass of about 125 kDa, which shows significant homology to the non-structural proteins of carmoviruses of the (+)ssRNA virus family *Tombusviridae*. Interestingly, transcripts derived from full-length cDNA clones were infectious when inoculated in spheroplasts and the transfected isolates exhibited phenotypic traits similar to the naturally infected isolate.

SmV A found in *Sclerophthora macrospora*, the pathogenic fungus responsible for downy mildew of gramineous plants, is a small icosahedral virus containing three segments of (+)ssRNAs (RNAs 1, 2, and 3). RNA 1 has two ORFs, one of which contains the RdRP motifs, and RNA 2 codes a single ORF for CP, while RNA 3 has any ORFs suggesting it is a satellite-like RNA. Whereas the deduced amino acid sequence of RdRP shows some similarity to RdRPs of members of the family *Nodaviridae*, the amino acid sequence of the viral CP shows similarity to those of members in the family *Tombusviridae*. The capsid of SmV A is composed of two protein species, named CP 1 and CP 2, both encoded in the same ORF in RNA 2. CP 2 is apparently derived from CP 1 via proteolytic cleavage at the N-terminus. The genome organization of SmV A is distinct from those of other known fungal RNA viruses, and suggest that SmV A should be classified into a novel genus of (+)ssRNA viruses.

SmV B, which is also found in *S. macrospora*, has small icosahedral, monopartite virions containing a (+)ssRNA species as a genome. The viral genome has two large ORFs; ORF1 encodes a putative polyprotein containing the motifs of chymotrypsin-related serine protease, and ORF2 encodes a CP. The genome arrangement of SmV B is similar to those belonging to the genera *Sobemovirus*, *Barnavirus*, and *Polerovirus*. The putative domains for the serine protease, VPg (the viral protein linked to the genome), RdRP, and the CP are located in this order from the 5′ terminus to the 3′ terminus. SmV B, however, is distinctive since its genome has only two ORFs, but the others have at least four ORFs. The genome organization of the barnavirus MBV, on the other hand, resembles that of poleroviruses. These results suggest that SmV B, like SmV A, should also be classified into a new genus of (+)ssRNA viruses.

Several unclassified (–)ssRNA viruses distantly related to ophioviruses, which are filamentous plant viruses within the family *Aspiviridae* known to be transmitted by the soil-inhabiting fungus *Olpidium virulentus*, have been reported. Examples include *Fusarium poae* negative-stranded RNA virus 1 and *Rhizoctonia solani* negative-stranded RNA virus 1 and unclassified bunyaviruses (order *Bunyavirales*) such as *Macrophomina phaseolina* negative-stranded RNA virus 1 and *Botrytis cinerea* negative-stranded RNA virus 1.

The mycoviruses belonging to the families *Pseudoviridae*, *Metaviridae*, *Reoviridae* (genus *Mycoreovirus*), *Totiviridae*, *Partitiviridae*, *Chrysoviridae*, *Megabirnaviridae*, *Quadriviridae*, *Hypoviridae*, *Mitoviridae*, *Narnaviridae*, *Barnaviridae* and *Myonnaviridae*, and the members of possible novel families such as *botybimaviruses* (genus *Botybimavirus*), *alternaviruses*, *fusariviruses* and *phlegiviruses* are discussed in more detail in separate articles in this work.

Replication and Gene Expression Strategy

Replication cycles of mycoviruses are not well studied except for a few cases including the prototype totivirus ScV-L-A. For dsRNA mycoviruses including members of the *Totiviridae*, *Partitiviridae*, *Reoviridae*, and *Chrysoviridae*, virus particles or subviral particles,

containing RdRP, are believed to play pivotal roles in RNA transcription and replication. Replication of capsidless (naked) (+)ssRNA mycoviruses represented by members of the family *Hypoviridae* may occur in infection-specific, lipid-membranous vesicles presumed to contain viral RdRP and RNA helicase. These vesicles are able to synthesize in vitro both plus and minus RNA at a ratio of 1:8. The narnaviral genomic RNA, encoding only a single protein (RdRP), is associated with RdRP forming an RNP structure rather than being encapsidated. These RNP complexes seem to play a key role in viral replication.

Mycoviruses, like many RNA viruses of plants and animals, employ non-canonical translational strategies for expressing their genomes. These include -1 frame shifting (totiviruses, trichomonasviruses and giardiaviruses in the *Totiviridae*), -2 frame shifting (trichomonasviruses in the *Totiviridae*), +1 frame shifting (*Pseudoviridae*, *Metaviridae*), presumable +1 frame shifting or ribosomal hopping (leishmaniviruses in the *Totiviridae*), termination-coupled initiation (stop/restart strategies; most of victoriviruses in the *Totiviridae*, *Hypoviridae*), IRES (internal ribosome entry site)-mediated initiation (*Totiviridae*, *Hypoviridae*, *Chrysoviridae*). In addition, proteases such as a cis-acting papain-like cysteine protease (*Hypoviridae*) and 2A-like self-processing peptides (yadokariviruses, probably giardiaviruses in the *Totiviridae* and some others) have also been known. Furthermore, a readthrough of a termination codon strategy is proposed for translation of the 3' proximal ORF of DRV. A non-canonical mechanism may also be required for efficient translation of mRNA of narnaviruses, which lack poly(A) tails. The (CAA)_n repeats found at the 5'-untranslated region (UTR) of chrysoviruses are implicated in translation augmentation, as observed for the 5' UTR sequence of a plant alpha-like virus (tobacco mosaic virus, TMV; family *Virgaviridae*). This possibility needs to be tested, given the recent detection of IRES activities in the UTRs of chrysovirus genomic segments. Translation of the viral genes that are regulated by these mechanisms is considered critical for virus viability.

Recent Technical Advances in Fungal Virology

Fungal virology has been thwarted by many constraints on manipulation of fungal viruses. Many, if not all, plant and animal viruses can be inoculated into individuals/tissue cultures of plant and animal hosts. Some assays with those hosts allow quantitative detection of biologically active viruses. As for mycoviruses, it is rather rare to be able to inoculate into host fungi because of experimental limitations, which often makes the etiology of mycoviruses difficult to establish. Fungal cells have rigid cell walls and are usually difficult to digest for preparation of cell-wall free protoplasts ready for transformation or transfection. Even if protoplasts are made, their maintenance, as with animal cell culturing, is not possible. Furthermore, fungal hosts usually have self/non-self recognition systems operating at inter- and intraspecies levels. Intraspecies barriers are based on vegetative incompatibility/compatibility governed genetically. This is often regarded as one of the host defense barriers that inhibit virus transfer between individuals. To overcome these barriers, a few methods are available. The prototypic hypovirus CHV1 is the first for which a reverse genetics is established. Infection with different CHV1 strains can be launched either from cDNA integrated into host chromosomes or in vitro synthesized viral RNA from the cDNA template. It is noteworthy that via bombardment of mycelia, not protoplasts, the infectious CHV1 cDNA clone can be integrated into chromosomes of fungi other than the natural host *C. parasitica*. cDNA-based transfection systems are now available for other RNA viruses such as DRV (a tombus-like virus), *Saccharomyces cerevisiae* 20S narnavirus (ScNV-20S), *Saccharomyces cerevisiae* 23S narnavirus (ScNV-23S), *Sclerotinia sclerotiorum* uormia-like virus 4, *Sclerotinia sclerotiorum* hypovirus 2, and Yado-kari virus 1 (a calici-like virus).

Mycoviruses in general lack infectivity as purified virions. However, all three members of the genus *Mycoreovirus* including MyRV1, MyRV2 and mycoreovirus 3 (MyRV3, from an *R. necatrix* strain) were found to be infectious as purified particles when applied to fungal protoplasts. It is of interest in this regard that treatment of purified virions with trypsin or chymotrypsin was not required for infectivity. Protoplast fusion provides an alternative approach to introduce mycoviruses into vegetatively incompatible fungal strains that are incapable of hyphal anastomosis. Intra- and interspecies virus transfer via protoplast fusion has been reported in *Aspergillus* spp., *Fusarium* spp. and *Cryphonectria* spp. This method is particularly useful for mycoviruses for which infectious particles or cDNA-derived RNA are unavailable. Another recent revelation is that monokaryotic strains are able to serve as an intermediate mycovirus transmitter between different mycelial incompatibility groups within the same species of *R. necatrix*.

To complete Koch's postulates, virus curing is as important as virus inoculation, because virus must be back inoculated into an isogenic, virus-free strain with the same genetic background as the original virus-infected strain. Virus-free isolates may be obtained from germings of asexual spores if virus transmission through spores is less than 100%. Alternatively, virus-free strains may be isolated by hyphal tip culturing, as in the case for *H. mompa* and *R. necatrix*. This technique is applicable to fungi infected with a virus that is transmitted to 100% of the asexual spores or for fungi that produce little or no spores. Protoplasting is also useful for virus curing. These curing methods can be employed in the presence of antiviral drugs such as ribavirin.

Future Perspectives

Cross-Kingdom Infection by Viruses and Viroids

The ssDNA mycovirus SsHDV1 was the first fungal virus that was shown to be replicated in and transmitted by a mycophagous insect, *Lycoriella ingenua*. Naturally this fly likely serves as a vector of the virus lateral transfer between fungi and also retains the virus across generations through vertical (transovarial) transmission. Of note is that this DNA virus in the purified or crude

preparation can extracellularly enter host mycelia on synthetic media. This feature contributes to field-level virocontrol of rapeseed rot caused by *S. sclerotiorum*.

Other examples of cross-kingdom infections involving mycoviruses include infection of a phytopathogenic basidiomycete, *Rhizoctonia solani*, by one of the best-studied plant viruses, cucumber mosaic virus (CMV, family *Bromoviridae*). The virus is apparently maintained stably in fungal colonies and is transmitted between plants. Namely, not only aphids (Hemiptera; a non-persistent manner) but also fungi act as virus vectors. Furthermore, a two-way facilitative interaction between a plant and fungal alpha-like viruses (TMV and CHV1) has been demonstrated, which could promote cross-kingdom virus infections in both directions. Viroids which are omnipresent plant pathogens having minimal non-protein-coding circular RNA genomes and were not detected from other kingdoms of organisms is also an example. However, hop stunt viroid (HSVd, *Pospiviroidae*), iresine 1 viroid (*Pospiviroidae*) and avocado sunblotch viroid (*Ausunviroidae*), which replicate in the nucleus, nucleus and chloroplast of their plant hosts, respectively, can establish stable infection in a few phytopathogenic fungi including *C. parasitica* and *Valsa mali*, and *F. graminearum*. Interestingly HSVd induces severe growth defects in *V. mali*, but not in the other two fungi.

These examples of cross-kingdom infection provide another layer of research direction. The antiviral RNA silencing is the primary defense mechanism in fungi, invertebrates (such as insects, mites and nematodes) and plants, while key players and mechanisms involved are different in these host organisms. How single viruses counter-defense is an interesting problem to address. Movement proteins are essential for plant viruses to establish a systemic infection in plant hosts, but not for the systemic infection by fungal viruses of fungal hosts. Genome alterations that may occur during long-term maintenance exclusively single kingdom of hosts is worth monitoring. There are a few genera that accommodate fungal viruses and viruses infecting members of other kingdoms such as plants and insects. It will be of great interest to elaborate on their experimental host ranges.

Yeast as a (Model) Host to Study Viral Replication

S. cerevisiae has provided an excellent system to investigate virus assembly and replication of the dsRNA totivirus (ScV-L-A) and the ssRNA narnaviruses (ScNV-20S and ScNV-30S) that infect yeast. With the robust yeast genetics, a number of host factors involved in totivirus replication were identified, many of which are related to translation events (see article on the yeast ScV-L-A for details). Furthermore, the yeast provides an “artificial” viral host model system to explore host genes affecting viral replication on a genome-wide basis. Genetic screens of a collection of 4500–4800 single-gene deletion yeast strains (Yeast Knockout strain collection) have been successfully conducted for identifying host factors involved in replication and recombination with two different tri- and monopartite plant (+)ssRNA viruses, brome mosaic virus (family *Bromoviridae*) and tomato bushy stunt virus (TBSV, family *Tombusviridae*), respectively. Each screen led to the identification of approximately 100 host genes (approximately 1.8% of the entire yeast genes) that affect virus replication. Interestingly, the replication of the two viruses in yeast is affected by a different set of genes. A similar approach was employed to identify genes affecting the recombination of TBSV. This type of use of the yeast system can be expanded to an animal (+) ssRNA virus and a vertebrate (–)ssRNA virus. Recent interesting screening of bacterial effectors, whose targets are known, for antiviral effects in yeast revealed pro- and anti-viral host factors for TBSV replication. It may be surprising that the yeast has yet to be used for viruses infecting filamentous fungi. The yeast should be able to serve as a model host for mycoviruses other than those that naturally infect yeast.

Virus Neo-Lifestyles

Recent mycovirus hunting revealed unique virus lifestyles. The first such lifestyle (called “neo-lifestyle”) is exhibited by a (+) ssRNA mycovirus termed yadokari virus 1 (YkV1) hosted by a dsRNA mycovirus called yado-nushi virus 1 (YnV1). YkV1 encodes RdRP but depends on YnV1 for its encapsidation. The replication and transcription of YkV1 are hypothesized to occur in the YnV1 capsid encasing YkV1 RNA (heterocapsid), thus YkV1 behaving like a dsRNA virus. Intriguingly YkV1 enhances the accumulation of the partner YnV1. YnV1 as a full-fledged dsRNA can complete its replication cycle. There appear to be YkV1-like viruses showing partnership with dsRNA viruses in other filamentous fungi.

Another virus neo-lifestyle was discovered in *Aspergillus fumigatus* (one of the most ubiquitous saprophytic ascomycete) infected by a tetra-segmented RNA virus *Aspergillus fumigatus* polymycovirus 1 (AfuPmV1, family *Polymycoviridae*). AfuPmV1 RdRP has the presumed catalytic amino acid sequence, GDNQ, similar to those of (–)ssRNA viruses (most of mononegaviruses), but is phylogenetically closer to (+)ssRNA viruses such as caliciviruses than to (–)ssRNA viruses. AfuPmV1 is assumed to be associated in a colloidal form with a virally encoded proline-alanine-serine rich protein (PASrp) rather than being encased by capsid protein. More surprisingly, AfuPmV1 is infectious as a purified naked dsRNA as well as a dsRNA/PASrp complex that appears to prevent viral dsRNA from being exposed to RNase. A virus closely related to AfuPmV1 has recently been discovered which is termed Hadaka virus 1 (HadV1). However, HadV1 has an 11-segmented (+)ssRNA genome but lacks a PASrp-encoding segment. Unlike polymycoviruses, HadV1 appears to be accessible in infected mycelial homogenates by nuclease.

Host Defense Against Mycoviruses and Their Counter-Defense

Host defense responses against viruses have not been explored intensively. RNA silencing is regarded as one of the host defense strategies of eukaryotes against molecular parasites including viruses, and has been shown to operate as antiviral defense in a

number of fungi including important models and phytopathogenic fungi. As in the case of other eukaryotes, deficiencies of antiviral-RNA silencing in fungal hosts result in severer symptom induction and enhanced mycovirus replication. There are genetic elements involved in RNA silencing that are conserved widely from fungi to vertebrates. The functional roles of these factors in RNA silencing as antiviral reactions appear to be different between fungi. Two genes, one Dicer gene, dicer-like 2 (*dcl2*), and one Argonaute gene, argonaute-like 2 (*agl2*), are required for antiviral responses in *C. parasitica*, while more players are involved in other fungi such as *F. graminearum* and *S. sclerotiorum*, where at least two Dicer genes (*dcl1* and *dcl2*) and Argonaute genes (*ago1* and/or *ago2*) are involved in the defense redundantly.

The RNA silencing key genes, *agl2* and *dcl2*, of *C. parasitica* are highly induced by over 10-fold on infection by some mycoviruses. This transcription upregulation is mediated by the SAGA complex, a general transcriptional co-activator, that requires DCL2 that, thus, plays a positive feedback role. DCL2 is necessary for the SAGA-mediated upregulation of not only *agl2* and *dcl2* but also many other fungal host genes. Some of the induced host genes contribute to symptom mitigation. The elevated state of antiviral RNA silencing established by a pre-infected virus can eliminate horizontal transmission via hyphal fusion and replication of a second virus susceptible to RNA silencing.

The protein p29 encoded by hypovirus CHV1 has been shown to be a suppressor of RNA silencing targeting a transgene that functions in both plant and fungal cells. In fungal cells, CHV1 p29 suppresses the above mentioned transcriptional upregulation of antiviral silencing key genes (*dcl2* and *agl2*). Unraveling the mechanism by which the CHV1 p29, or other mycovirus-encoded RNA silencing suppressors, may block the RNA silencing pathway will be a very interesting challenge.

Other layers of host defense include vegetative incompatibility which impairs lateral virus transmission between colonies of a single species. This non-self allorecognition is governed genetically, in the case of *C. parasitica*, 6 diallelic loci (*vic*), and therefore, serves as a barrier against virocontrol. It is worth noting that super donor strains with deletions of multiple *vic* genes allow efficient mycovirus transmission at the field level. Non-self-responses include programmed cell death in which reactive oxygen species play a pivotal role. Some mycoviruses are able to suppress vegetative incompatibility reactions in fungi.

Role of Mycoviruses in Plant-Fungal Mutualistic Associations

The question of whether mycoviruses are involved in the mutualistic interactions between endophytic fungi and their host plants is of considerable interest because of the attractive beneficial features of these associations and because of the common occurrences of mycoviruses in all major groups of fungi. This question was recently addressed in an intriguing report that presented evidence for a dsRNA mycovirus being involved in the mutualistic interaction between a fungal endophyte (*Curvularia protuberata*, an ascomycete) and a tropical panic grass (*Dichanthelium lanuginosum*). This association allows both organisms to grow at high soil temperatures. The virus in question, which was designated *Curvularia thermal tolerance virus* (CThTV, the proposed family “*Curvulaviridae*”), has unusual genome organization with an unknown genome expression strategy. CThTV has apparently a bipartite dsRNA genome (RNA1 and RNA2), but no evidence that these RNAs are packaged in the 27-nm isometric particles isolated from the fungal host. Although many questions pertinent to the fungal endophyte, CThTV, and the veracity of the evidence for viral etiology remain unanswered, this report will undoubtedly stimulate the search for mycoviruses in other mutualistic fungal endophytes. In this regard, it is noteworthy that the well-characterized mutualistic ascomycete endophyte, *Epichloë festucae*, was found to harbor a totivirus, but no phenotypes were associated with virus infection.

S. sclerotiorum is a destructive ascomycetous pathogen in many dicotyledonous crops. However, the single-stranded DNA virus SsHADV1, known to induce hypovirulence in the host fungus *S. sclerotiorum*, causes a switch of the lifestyle of the fungal phytopathogen from a pathogenic to an endophytic status. Interestingly, treatments of rapeseed by SsHADV1-infected *S. sclerotiorum* promote plant growth compared to untreated plants, and has protective effects against virulent, virus-free fungal strains of *S. sclerotinia* but also its closely related species, *Botrytis cinerea*. These features of SsHADV1 together with horizontal transmissibility to vegetatively incompatible fungal strains make the virus a potentially robust virocontrol agent (see below). Surprisingly, *S. sclerotiorum* strain DT-8 infected by SsHADV1 grows endophytically in wheat (a monocotyledonous crop), previously believed to be a non-host of the fungus, and increases its grain yield. Furthermore, the fungal strain mitigates the symptoms induced by the *Fusarium* head blight disease (FHB) caused by *Fusarium graminearum* both in the laboratory and field conditions, likely through enhanced defense responses. Similar positive effects can be observed in other cereal monocotyledonous crops, such as rice and barley, against different ascomycetous pathogenic fungi such as *Magnaporthe oryzae*. Specific contribution of SsHADV-1 to this phenomenon is obscure, because these effects appear to be exerted whether *S. sclerotiorum* is infected by SsHADV1 or not.

Mycovirus as Biocontrol Agents and as Tools for Fundamental Studies

The hypovirulence phenotype in the chestnut blight fungus (*C. parasitica*) is an excellent and well-documented example of a mycoviral-induced phenotype that is currently being exploited for biological control. The debilitating disease of Victoria blight (*H. victorae*) and the disease phenotype of the Dutch elm disease fungus (*Ophiostoma novo-ulmi*, an ascomycete) are examples of pathogenic effects of dsRNA mycoviruses. The ssDNA virus, SsHADV has also attracted great attention because of its potential as a virocontrol (biocontrol) agent and its abilities to enter host fungal cells, be replicated in and be transmitted by the mycophagous fly. An understanding of the molecular basis of disease in these fungal-mycovirus systems would provide excellent opportunities for the development of novel biocontrol strategies of plant pathogenic fungi. Mycoviruses also continue to serve as versatile tools to study

the virulence of host fungi, as recognized in studies with the hypovirus/*Cryphonectria* system, in which substantial advances in our understanding of the molecular basis of hypovirulence have been made.

It should be noted that some mycoviruses enhance virulence (hypervirulence), sporulation, and mycelial growth. For example, virus-induced hypervirulence was observed in the *Nectria radicola* mycovirus system. The host fungus causes root rot in ginseng (*Panax quinquefolius*). Another example is the virus (a chrysovirus)-enhanced production of the host-specific toxin (AK-toxin) of *Alternaria alternata* (an ascomycete) that causes black spot in Japanese pear.

Introduction

Viruses, like other obligate parasites, depend on host organisms for their multiplication and survival. As the hosts do not live forever, the continued existence of viruses in the population is maintained by transmission between individual organisms. The extent to which viruses spread is largely influenced by their host range, transmission pathways, and environmental conditions. The compatibility of virus-host cell interactions, host defenses and the ability of the viruses to counter or evade defense responses are critical in determining viral host range. Viruses can infect new hosts through genetic mutations that enhance their compatibility with host cellular components or enable them to evade host defenses. Furthermore, the mode of virus transmission is also a major factor controlling virus spread. As such, the mobility of biological vectors, human activities, and changes of environmental conditions may increase the possibility of contact between viruses and a potential novel host.

Viruses are known to spread between species; however, virus transfer across kingdoms is previously thought to be less common and naturally occurring cross-kingdom infection by a virus species is rarely documented. There are several classic examples of virus groups that infect hosts belonging to different taxonomical kingdoms, but they are mostly limited to some plant virus groups that replicate in their insect vectors. Nevertheless, certain viruses appear to have an inherent ability to infect different domains of life, as demonstrated by several reports of viruses artificially introduced to new hosts belonging to different biological kingdoms in the laboratory, particularly insect, plant, and fungal viruses. Moreover, several closely related viruses have been found to separately infect organisms of different kingdoms, such as some viruses infecting plants and fungi. This suggests horizontal virus transfer across kingdoms at some time in the past. Thus cross-kingdom viral infections represent an event that has happened before and might happen again.

The distinct biological characteristics of different kingdoms create natural barriers for virus horizontal transfer. Even so, agricultural practices and other human activities have caused drastic changes to the biological and ecological systems of the world. Such a situation might create conditions that conceivably could facilitate cross-kingdom viral infection in the environment. Such a scenario raises concerns for the possible emergence of new animal and plant diseases in the future.

This article summarizes cross-kingdom virus infection of plant, insect, and fungal viruses. The topics cover experimental, ecological and evolutionary aspects of virology.

Viruses That Replicate in Both Plants and Insects

There are some plant virus groups that are known to be transmitted in a persistent propagative manner by their arthropod vectors, and thus they replicate both in plant hosts and insect vectors (**Fig. 1**). They are predominantly negative-sense single-stranded RNA viruses ((–)ssRNA viruses; plant rhabdoviruses, tospoviruses, and tenuiviruses), and segmented double-stranded RNA viruses (dsRNA viruses; plant reoviruses). There are also a small portion of non-segmented positive-sense single-stranded RNA viruses ((+)ssRNA viruses; marafiviruses). Some studies showed that infection by certain plant viruses altered the performance of their insect vectors, such as for longevity, fecundity, and feeding behavior.

Classical plant rhabdoviruses (family *Rhabdoviridae*, order *Mononegavirales*, unsegmented (–)ssRNA viruses) belonging to the genera *Cytorhabdovirus* (type species *Lettuce necrotic yellows cytorhabdovirus*) and *Nucleorhabdovirus* (type species *Potato yellow dwarf nucleorhabdovirus*) infect diverse plants including cereal, maize and several vegetables. They are similarly transmitted by aphids (family *Aphididae*, order *Hemiptera*) such as the cabbage aphid (*Brevicoryne brassicae*) and the sowthistle aphid (*Hyperomyzus lactucae*), leafhoppers (family *Cicadellidae*, *Hemiptera*) such as the green rice leafhopper (*Nephotettix* spp.) and the black-faced leafhopper (*Graminella nigrifrons*) and planthoppers (family *Delphacidae*, *Hemiptera*) such as the small brown planthopper (*Laodelphax striatellus*) and the corn planthopper (*Peregrinus maidis*). Members of the newly established genus *Dichorhavirus* (type species *Orchid fleck dichorhavirus*, two-segmented (–)ssRNA viruses) are transmitted by false spider mites (*Brevipalpus* spp., *Tenuipalpidae*) and are also likely to replicate in their vectors.

Genus *Orthotospovirus* (formerly *Tospovirus*, type species *Tomato spotted wilt orthotospovirus*, segmented (–)ssRNA viruses) in the family *Tospoviridae* (order *Bunyavirales*) contains several members that infect a wide range of plants. They are exclusively transmitted by thrips (family *Thripidae*, order *Thysanoptera*) such as the western flower thrip (*Frankliniella occidentalis*), the onion thrip (*Thrips tabaci*), and the melon thrip (*T. palmi*). The plant hosts of the members of genus *Tenuivirus* (type species *Rice stripe tenuivirus*, segmented (–)ssRNA viruses) in the family *Phenuiviridae* (order *Bunyavirales*) are limited to the family *Poaceae* such as rice and maize, and these viruses are propagatively transmitted by planthoppers such as *L. striatellus*, *P. maidis*, and the brown planthopper, *Nilaparvata lugens*.

Plant-infecting reoviruses (segmented dsRNA viruses) are classified into 3 genera, *Phytoreovirus* (type species *Wound tumor virus*), *Fijivirus* (type species *Fiji disease virus*), and *Oryzavirus* (type species *Rice ragged stunt virus*) in the family *Reoviridae*, and they mainly

Viral proteins required for cell-to-cell movement in the plant or vector transmission/infection to the insect vector are presented below the arrow. *Forms tubules facilitating viral spread among insect vector cells. **Possible glycoprotein whose biological function is unknown.

infect the plant family Poaceae. Fijiviruses and oryzaviruses (subfamily *Spinareovirinae*) are propagatively transmitted by planthoppers such as *L. striatellus*, *N. lugens*, and the white-backed planthopper (*Sogatella furcifera*). Phytoreoviruses (subfamily *Sedoreovirinae*, lacking the large surface projection of virus particles) are propagatively transmitted by leafhoppers, such as *Nephotettix* spp., *Agallia* spp., and *Recilia dorsalis*. Members of the genus *Mirafivirus* (type species *Maize rayado fino virus*, plant alpha-like viruses) in the family *Tymoviridae* (order *Tymovirales*) infect diverse host plants including maize, citrus and oat. The corn leafhopper (*Dalbulus maidis*) is known as an efficient vector for maize rayado fino virus. Interestingly, a recent report showed that tobacco ringspot virus (family

Secoviridae, order *Picornavirales*), a plant picorna-like virus with a two segmented (+)ssRNA genome, could replicate in honeybees, *Apis mellifera* (family *Apidae*, Hymenoptera) and spread throughout the entire body of the insect.

Orthospoviruses and classical plant rhabdoviruses have enveloped spherical (~80–110 nm in diameter) and bacilliform (~300–350 nm long and ~75–100 nm in diameter) virions, respectively. Viral membranes are likely required for the entry of viruses into insect cells but not into plant cells. Viral membrane glycoproteins of plant nucleo- and cytorhabdoviruses (G protein) and orthospoviruses (G_N and G_C proteins) are embedded in the outer-membrane envelope and they are believed to be involved in virus entry, interacting with receptor proteins on the insect cell surface. Similarly, P2 and VP9 encoded by phyto-reoviruses and oryzaviruses, respectively, are components of the outer capsid protein that bulge from the surface of the double-shelled virion (~60–100 nm in diameter) and are involved in infection of insect. In addition, these plant- and insect-infecting viruses encode cell-to-cell movement proteins that are specifically required for spread of viruses through host plants (Fig. 1). Notably, an insect small RNA virus, flock house virus (FHV, family *Nodaviridae*, a small non-enveloped spherical virion with a two-segmented (+) ssRNA genome) is able to replicate in mechanically inoculated leaves of several plant species; however, systemic spread of FHV throughout the plant requires expression of a plant virus-encoded cell-to-cell movement protein. Therefore, evidence suggests that these propagatively insect-transmitted viruses are characterized by biological properties required for successful infection in both plant and insect hosts.

Closely Related Viruses Independently Infect Plants and Fungi

There has been a surge of research interest in characterizing and studying fungal viruses, particularly those infecting plant pathogenic fungi. A growing number of newly identified fungal viruses contribute greatly to our understanding of virus diversity and evolution. For example, a number of fungal viruses were found to have close similarities with plant viruses, suggesting horizontal transfer of these viruses between plants and fungi in the not so distant past. One of the most striking observations is that some plant and fungal partitiviruses (family *Partitiviridae*, picorna-like viruses with a segmented dsRNA genome and non-enveloped spherical virion, 25–43 nm in diameter) show close sequence similarities. Phylogenetic analysis shows that plant and fungal partitiviruses were placed together in some clades of alpha- and betapartitiviruses, in addition to clades containing either plant or fungal partitiviruses (Fig. 2(A)). Therefore, some partitiviruses from different kingdoms, plant and fungi, are more similar to each other than to those from within a single kingdom. Additionally, the similarity between plant- and fungus (or oomycetes, including *Phytophthora* spp.) infecting endornaviruses (family *Endornaviridae*, capsid-less alpha-like (+)ssRNA viruses) has been observed. The members of plant partiti- and endornaviruses can establish persistent infections in host cells but lack a typical cell-to-cell movement protein. It is proposed that viruses that cause persistent infections of plants, such as partitiviruses, could have originated from fungal viruses that infect plant associated fungi, including endophytes.

Another finding is that a fungal alpha-like virus, Botrytis virus X (genus *Botrexvirus*, family *Alphaflexiviridae*, *Tymovirales*, a filamentous virion with non-segmented (+)ssRNA genome) isolated from the gray mold fungus *Botrytis cinerea* (family *Sclerotiniaceae*), a necrotrophic plant pathogenic ascomycete, shows close sequence similarity to allxiviruses (genus *Allexivirus*, *Alphaflexiviridae*, plant alpha-like viruses with a filamentous virion) that encode a gene block for a cell-to-cell movement protein and mainly infect the plant genus *Allium* (garlic and onion; Fig. 2(B)). As *B. cinerea* commonly infects horticulture plants including *Allium* spp., it is speculated that *B. cinerea* might have acquired a plant allxivirus or a progenitor during an infection.

Artificially Established Viral Cross Infections Between Plants and Fungi

Pioneering work by Paul Ahlquist established a replication system for a plant alpha-like virus, brome mosaic virus (BMV, family *Bromoviridae*, a tripartite (+)ssRNA genome) in yeast *Saccharomyces cerevisiae*. This has since been achieved for other plant viruses, including tomato bushy stunt (TBSV), Cymbidium ringspot (CymRV), and carnation Italian ringspot viruses (CIRV) (family *Tombusviridae*, with a non-segmented (+)ssRNA genome; Table 1). Replication of these viruses takes place on intracellular membranes derived from organelles in both plant and yeast cells; BMV uses endoplasmic reticulum (ER) membranes, TBSV and CymRV use peroxisomal membranes and CIRV uses mitochondrial membranes. In addition, in the absence of the peroxisomal membrane, TBSV and CymRV can utilize ER membranes for their replication in yeast. Notably, some animal (+)ssRNA viruses (FHV and Nodamura virus, a nodavirus) and DNA viruses (human and bovine papillomaviruses, family *Papillomaviridae*, and adeno-associated virus, family *Parvoviridae*, circular dsDNA and ssDNA genome, respectively) were also shown to replicate in yeast cells.

More recently, some reports show replication of two plant alpha-like viruses, tobacco mosaic virus (TMV, family *Virgaviridae*, non-segmented (+)ssRNA genome) and cucumber mosaic virus (CMV, *Bromoviridae*, tripartite (+)ssRNA genome; see also below), in plant pathogenic filamentous fungi (Table 1). However, it was also shown that CMV was not able to stably infect two other plant pathogenic filamentous fungi, *Cryphonectria parasitica* (family *Cryphonectriaceae*, *Diaporthales*) and *Fusarium graminearum* (family *Nectriaceae*), causal agents of chestnut blight and fusarium head blight diseases, respectively. This demonstrated that there was a fungal-specific host compatibility of CMV infection. TMV virion (non-enveloped rod shape particles, 300 nm long and 18 nm in diameter) enters the fungal hyphae and/or conidia during culture by an unknown mechanism, and virus replication does not alter the pathogenicity and growth of the host fungus. Conversely, two fungal viruses, *Penicillium aurantiogriseum* partiti-like virus 1 and *Penicillium aurantiogriseum* totivirus 1, from a marine plant endophyte (*Penicillium aurantiogriseum*, family

Fig. 2 Phylogenetic relationships of selected plant- or fungus-infecting viruses belonging to families *Partitiviridae* (A) and *Tymoviridae* (B). Maximum likelihood phylogenetic trees were constructed using PhyML 3.0 based on the multiple amino acid sequence alignment of the replicase protein or its candidate sequences. A model LG + I + G + F was selected as the best-fit model for the tree construction. Clades for beta-, gamma-, deltapartitviruses, betaflexi- and tymoviruses are shown by collapsed branches with triangles.

Table 1 The list of viruses used for artificial cross-kingdom infections between plants and fungi

Virus	Original host	New host	Method of virus introduction
Brome mosaic virus (genus <i>Bromovirus</i>)	Plant (<i>Bromus inermis</i> and other grasses)	<i>Saccharomyces cerevisiae</i>	Cell/spheroplast transformation
Tomato bushy stunt virus (genus <i>Tombusvirus</i>)	Plant (mainly vegetables crop and ornamental plants)	<i>S. cerevisiae</i>	Cell/spheroplast transformation
Carnation Italian ringspot virus (genus <i>Tombusvirus</i>)	Plant (some ornamental plants and fruit trees)	<i>S. cerevisiae</i>	Cell/spheroplast transformation
Cymbidium ringspot virus (genus <i>Tombusviruse</i>)	Plant (<i>Cymbidium</i> and clover)	<i>S. cerevisiae</i>	Cell/spheroplast transformation
Mung bean yellow mosaic India virus (genus <i>Begomovirus</i> , family <i>Geminiviridae</i>)	Plant (legume)	<i>S. cerevisiae</i>	Cell/spheroplast transformation
Tobacco mosaic virus (genus <i>Tobamovirus</i>)	Plant (a very wide host range)	<i>Colletotrichum acutatum</i> , <i>C. clavatum</i> , <i>C. theobromicola</i>	Virus particles added to liquid medium
Cucumber mosaic virus (genus <i>Cucumovirus</i>)	Plant (a very wide host range)	<i>Rhizoctonia solani</i> , <i>Valsa mali</i>	Spheroplast transformation
Penicillium aurantiogriseum totivirus 1 (unclassified toti-like virus)	<i>Penicillium aurantiogriseum</i>	<i>Nicotiana benthamiana</i> , <i>N. benthamiana</i> expressing a silencing suppressor (HC-Pro), <i>N. tabacum</i> (BY2 culture cells)	Protoplast transformation
Penicillium aurantiogriseum partiti-like virus (unclassified partiti-like virus)	<i>Penicillium aurantiogriseum</i>	<i>N. benthamiana</i> expressing a silencing suppressor (HC-Pro), <i>N. tabacum</i> (BY2 culture cells)	Protoplast transformation

Trichocomaceae) can replicate in plant cells (Table 1). These reports demonstrate the compatibility between certain plant viruses and fungal cells, as well as between certain fungal viruses and plant cells.

Evidence of the Natural Transmission of a Plant Virus to a Fungus

The first report of the natural infection of a fungus with a plant virus was the discovery of CMV (plant alpha-like virus) infecting a field strain of the plant pathogenic basidiomycete fungus, *Rhizoctonia solani* (family Ceratobasidiaceae). During an attempt to identify fungal viruses infecting several strains of *R. solani* collected from potato fields, one fungal strain was found to be coinfecting with CMV, in addition to other fungal viruses. Further analysis confirmed that CMV infection was stable in this fungal strain and the virus was horizontally transmitted through hyphal anastomosis, but not vertically through basidiospores. In addition, CMV was also shown to replicate in an ascomycete fungus, the apple canker fungus (*Valsa mali*, family Valsaceae, Diaporthales). Therefore, many phytopathogenic fungi may support stable infection of this virus. Under laboratory conditions, it was demonstrated that *R. solani* could acquire CMV from virus-infected potato and *Nicotiana benthamiana*, as well as transmit the virus to uninfected plants. This supported the notion that CMV was transferred from plant to *R. solani* during infection in the natural environment. Interestingly, CMV infection has no effect on *R. solani* growth and morphology in artificial culture media, but infection of plants by the *R. solani* strain carrying CMV induces more severe symptoms than the virus-free strain. Thus, acquiring CMV seems to make *R. solani* more aggressive which has implications for disease control.

It is still not clear how CMV transfers between plant and fungi during infection. As a necrotrophic pathogen, *R. solani* decomposes the host cells for uptake of nutrients. This possibly allows the transfer of relatively big molecules, such as CMV particles (~28 nm in diameter), from the plant cell into fungal cells. Because CMV is infectious in the form of RNA, it is also possible that CMV is transmitted in the form of naked RNA or ribonucleoprotein.

A Fungal DNA Virus That Replicates in an Insect and Uses It as a Vector

Sclerotinia sclerotiorum hypovirulence-associated DNA virus 1 (SsHADV-1), the first DNA virus discovered in fungi, was isolated from a hypovirulent strain of *Sclerotinia sclerotiorum* (family Sclerotiniaceae), an ascomycete fungal plant pathogen known as the white mold fungus. SsHADV-1 belongs to the genus *Gemycircularvirus* (family *Genomoviridae*, a circular ssDNA genome and non-enveloped spherical particles about 20 nm in diameter) whose members are found in various environments, as well as in plant- and animal-associated samples. It was observed that the mushroom fly *Lycoriella ingenua* (family *Sciaridae*, order *Diptera*), an insect that feeds on fungi, could acquire SsHADV-1 when the larvae were fed on virus-infected fungal colonies. SsHADV-1 replicates in *L. ingenua* cells and the virus is transmitted vertically to *L. ingenua* offspring. Under laboratory conditions, *L. ingenua* could transmit SsHADV-1 to virus-free *S. sclerotiorum* and SsHADV-1 was detected in adult *L. ingenua* collected from the field, suggesting that SsHADV-1 could use *L. ingenua* as a vector.

Fig. 3 A diagram showing known examples of natural transmission of viruses among animal, plant and fungal kingdoms. CMV, cucumber mosaic virus; SsHADV-1, *Sclerotinia sclerotiorum* hypovirulence-associated DNA virus 1.

Given that SsHADV-1 was also detected in two dragonfly species (*Erythemis simplicicollis* and *Pantala hymenaea*, family Libellulidae) and one damselfly species (*Ischnura ramburii*, family Coenagrionidae; order Odonata), and SsHADV-1-related viruses were found in other insects, it is possible that other insects in addition to *L. ingenua* are natural hosts of SsHADV-1. Many insects feed on fungi or are infected with fungi; therefore, horizontal transfer of viruses between insect and fungus may not be specific, but could occur frequently in nature.

The Contribution of Cross-Kingdom Viral Infection to Virus Evolution

The current understanding of RNA virus lineages signifies pervasive horizontal virus transfer between diverse hosts as critical points in RNA virus evolution. Instances where RNA virus groups infect diverse hosts, including organisms of different taxonomic kingdoms includes the ourmiaviruses, plant infecting tripartite (+)ssRNA viruses (genus *Ourmiavirus*, family *Botourmiaviridae*, non-enveloped bacilliform virions with discrete lengths from 30 to 62 nm), that are related to narnaviruses (genus *Narnavirus*, family *Narnaviridae*, capsid-less (+)ssRNA viruses) infecting fungi (budding yeast and filamentous ascomycetes) and oomycete (*Phytophthora infestans*, family Peronosporaceae), and ourmia-like viruses recently discovered from invertebrate and fungi. Thus, ourmiaviruses seem to have evolved from horizontal transfer of narnaviruses or ourmia-like viruses to plants together with the acquisition of genes responsible for viral cell-to-cell movement and capsid formation. *Secoviridae* (non-segmented (+)ssRNA viruses with non-enveloped spherical particles 25–30 nm in diameter), a large virus family limited to plant hosts, belongs to the clade of picorna-like viruses (non-segmented (+)ssRNA genome) infecting a variety of invertebrates, mainly arthropods, suggesting ancestral secoviruses evolved in their host plants after horizontal transfer from arthropods. Furthermore, the genome segmentation of their ancestor may have occurred simultaneously with this event except for the members of genera *Waikavirus* and *Sequivirus*. Likewise, plant rhabdoviruses (family *Rhabdoviridae*, (–)ssRNA viruses) are most likely descended from insect rhabdoviruses because they tend to group according to their insect vectors rather than their host plants. Interestingly, the segmented-genome type of rhabdoviruses (dichorhaviruses), which is similar to the segmented genome feature of many plant viruses, is only known to exist in plants, suggesting evolution of rhabdoviruses in their host plants after horizontal transfer. Recently established viral phylogenies using expansive virus metagenomic data showed unprecedented clustering of plant and invertebrate virus groups, further implying pervasive horizontal virus transfers from invertebrates to plants in the distant past.

Concluding Remarks

Increasing evidence supports the view that some viruses can infect hosts from different kingdoms such as insects, plants and fungi and that may be rather common in nature. Viral phylogenies suggest that virus transmission across kingdom barriers has occurred in the past. In addition, artificial virus inoculation methods have demonstrated that certain viruses are able to replicate in both plants and fungi. Most importantly, examples of natural virus transmissions between insects and plants or fungi, as well as between plants and fungi, have been documented (Fig. 3). Further experimental and ecological studies on cross-kingdom virus infections would deepen our understanding of the origin, host range, dissemination and reservoir of viruses in the environment.

Glossary

Anamorph The asexual reproductive stage of a fungus.

Anastomosis Fusion between branches of hyphae.

Ascocarp Fruiting body of a fungus belonging to the phylum Ascomycota, containing asci filled with ascospores.

Ascospore Sexual spore of a fungus belonging to the phylum Ascomycota, produced inside a sac called an ascus.

Conidiospore Asexual spore of a fungus.

Heterokaryon A multinucleate fungal cell that contains genetically different nuclei.

Heterothallic fungus Fungus not possessing, within a single individual, the resources to reproduce sexually but requiring two distinct individuals of opposite mating types.

Homothallic fungus Fungus possessing, within a single organism, the resources to reproduce sexually.

Teleomorph The sexual reproductive stage of a fungus.

Introduction

Aspergillus is a genus of filamentous fungi belonging to the order Eurotiales, class Eurotiomycetes, phylum Ascomycota. Genus *Aspergillus* includes the anamorphs (asexual stage) of more than 250 species, although some of them are known to also have a teleomorph (sexual stage) belonging to a different genus. For example, *Emericella nidulans* is the teleomorph of *A. nidulans*. Anamorphic fungi reproduce by producing conidiospores, asexual spores, while teleomorphs belonging to the phylum Ascomycota develop ascocarps, fruiting bodies producing ascospores, sexual spores. *Aspergilli* have a worldwide distribution, are ubiquitous and able to occupy numerous niches in terms of temperature, osmotic stress, and nutrient availability, with most of them being saprophytic. Individual *Aspergillus* species are medically, ecologically, and economically important and *Aspergillus* is one of the most well studied fungi in the laboratory; for example, *A. nidulans* was used as a model organism to study fungal genetics and the parasexual cycle in the 1950s and it was also one of the first fungi to have its genome fully sequenced in 2005.

To date, twenty taxa, nineteen families (*Alphaflexiviridae*, *Amalgaviridae*, *Barnaviridae*, *Botourmiaviridae*, *Chrysoviridae*, *Deltaflexiviridae*, *Endornaviridae*, *Gammaflexiviridae*, *Genomoviridae*, *Hypoviridae*, *Megabirnaviridae*, *Metaviridae*, *Mymonaviridae*, *Narnaviridae*, *Partitiviridae*, *Pseudoviridae*, *Reoviridae*, *Totiviridae*, *Quadriviridae*) and one genus that does not belong to a family (*Botybirnavirus*), are officially recognized by the International Committee for the Taxonomy of Viruses (ICTV) to accommodate, exclusively or not, mycoviruses. With the exception of *Genomoviridae*, mycoviruses have linear double-stranded (ds) or single-stranded (ss) RNA genomes. Out of these twenty recognized taxa, only members of the families *Chrysoviridae*, *Partitiviridae*, *Narnaviridae*, and *Totiviridae* have been discovered in *Aspergilli* to date. Other mycoviruses identified that could not be accommodated to the already existing families were often provisionally assigned to proposed families, e.g., *Polymycoviridae*. In general, RNA mycoviruses do not have any known extracellular phase in their replication cycle; they can be transmitted vertically, from parent to offspring, *via* conidiospores and ascospores, and horizontally, from one fungal isolate to another, *via* anastomosis/hyphal fusion. Mycovirus infections are persistent and, once infected, it is very difficult for fungal hosts to eliminate mycoviruses. The majority of mycovirus infections are also asymptomatic, latent, or cryptic.

Prevalence

In *Aspergilli*, the presence of mycoviruses was initially reported in 1970, when spherical virus-like particles (VLPs) containing dsRNA were discovered in *A. foetidus* and *A. niger*. Notably, the mycoviruses infecting *A. foetidus* strain IMI 41871, known as the *A. foetidus* mycovirus complex, are among few fully described at the molecular level, although their characterization was completed only recently, 45 years following their initial discovery.

Since then, investigations have revealed the presence of dsRNA elements, often accompanied by VLPs, in *Aspergillus* sections Nigri, Circumdati, Flavi, and Fumigati. In the cases where large populations of fungi were examined, the percentage of infected isolates ranged from less than 10% to almost 50%, often dependent on the geographic origin of isolates from the same species. The number of dsRNA elements present in each isolate varied from 1 up to 9, suggesting that in at least some of the cases more than one mycovirus was present. The dsRNA elements ranged from less than 0.5 kbp to 10 kbp in size; however, in most instances, the dsRNA elements were not characterized at the molecular level and therefore no conclusions can be drawn regarding the evolutionary relationships among similarly sized segments. Finally, the diameter of the VLPs ranged from 23 to 40 nm.

In *Aspergillus* section Nigri or 'black *Aspergilli*', apart from *A. foetidus* and *A. niger*, the presence of mycoviruses has been reported in *A. awamori*, *A. carbonarius*, *A. heteromorphus*, *A. japonicus*, and *A. tubingensis*. The prevalence of mycoviruses appears to be particularly high in Indonesian isolates. In *Aspergillus* section Flavi, *A. flavus*, *A. leporis*, *A. nomius*, *A. parasiticus* and *A. tamarii*, are known to harbor mycoviruses. In *Aspergillus* section Circumdati, mycoviruses have been found in *A. ochraceus* and *A. petrakii*;

Aspergillus ochraceus virus (AoV) from strain FA0611 has been fully sequenced. Finally, mycoviruses have been reported in both clinical and environmental isolates of *A. fumigatus*. Six of them, *Aspergillus fumigatus* chrysovirus (AfuCV), *Aspergillus fumigatus* partitivirus 1 (AfuPV-1), *Aspergillus fumigatus* partitivirus 2 (AfuPV-2), *Aspergillus fumigatus* narnavirus 1 (AfuNV-1), *Aspergillus fumigatus* narnavirus 2 (AfuNV-2), *Aspergillus fumigatus* mitovirus 1 (AfuMV-1), and *Aspergillus fumigatus* tetramycovirus 1 (AfuTmV-1) have been characterized at the molecular level.

Despite the relative high prevalence of mycoviruses in a number of anamorphic *Aspergilli*, their reported presence in the teleomorphs of the genus *Aspergillus* is much rarer. No dsRNA elements were discovered in a large *E. nidulans* (teleomorph of *A. nidulans*) panel derived from worldwide locations. Nevertheless sporadic mycovirus infections have been reported for *Neosartorya hiratsukae*, *N. quadricincta* (teleomorphs of *Aspergillus* section Fumigati) and *Petromyces alliaceus* (teleomorph of *A. alliaceus*, *Aspergillus* section Flavi).

Additionally, it should be noted that the quantity and even the presence of mycoviruses at detectable levels often depend on the composition of the nutrients in the growth medium and the developmental stage of the fungus. Regarding the latter, there have been a range of reports: in some cases virus replication correlates with the abundance of nutrients in the exponential phase of fungal growth while in others the virus titer is higher at the more advanced stages of the life cycle of the fungus. These results should not necessarily be considered conflicting, since they were derived from different fungal species most likely harboring distinct mycoviruses.

Transmission

Over the years, *Aspergilli* have been used as a model system for investigating all aspects of mycovirus transmission, including vertical transmission *via* conidiospores and ascospores, horizontal transmission *via* anastomosis/hyphal fusion, the role of heterokaryon incompatibility between fungal isolates as a barrier to mycovirus spread and intraspecies transmission.

During the formation of conidiospores from the tip of a differentiated hyphae called the conidiophore, mycoviruses present in the cytoplasm can be trapped within the conidial cell wall. Subsequently, the conidiospores are released from the conidiophore, disperse through the air and eventually give rise to a new fungal colony which is infected with the mycovirus. All relevant studies have shown that vertical transmission of mycoviruses *via* conidiospores is highly efficient in *Aspergilli*. This ensures the maximal dispersion of mycoviruses, which, having no extracellular phase in their replication cycle depend on their host for movement, together with their survival under harsh environmental conditions when the cost-efficient conidiation is the reproductive method of choice.

In contrast, vertical transmission of mycoviruses *via* ascospores is far less efficient. For instance, dsRNA elements introduced in *E. nidulans* (teleomorph of *A. nidulans*) were present exclusively in ascospores produced by self-fertilization and not following crossing with a compatible partner. This observation explains the paucity of mycoviruses in *E. nidulans* and was also confirmed for *N. hiratsukae*. The wider implication is that mycoviruses would not be transmitted *via* ascospores by *Aspergillus* teleomorphs which are exclusively heterothallic (unable to self-fertilize) and not homothallic.

Horizontal transmission of mycoviruses from one fungal strain to another requires their physical proximity and the fusion of their hyphae, a process called anastomosis. Following anastomosis, the cytoplasm, the nuclei and other organelles of two fungal strains, together with any mycoviruses present, co-exist in a joint mycelium called a heterokaryon. When the heterokaryon breaks down to homokaryons, either by forming distinct uninucleate sectors or by conidiation, mycoviruses may be inherited from a previously virus-free strain. In *Aspergilli*, the co-existence of multiple different mycoviruses in the same host is possible; however already infected isolates may be able to accommodate additional dsRNA elements, potentially due to limiting competition with the established mycoviruses.

Notably, not all fungal strains can fuse their hyphae and form heterokarya and this heterokaryon (or vegetative) incompatibility may restrict mycovirus transmission. The (in)compatibility of fungal strains depends on a number of nuclear genes whose specific alleles determine whether anastomosis should be allowed. Nevertheless, no correlation between the presence of dsRNAs and the isolates' mitochondrial RFLP haplotype, specific conserved surface protein types or mating type MAT1-1 and MAT1-2 have been noted. In the case of *A. niger*, mycovirus transfer was possible between isogenic or vegetatively compatible strains following generation and fusion of protoplasts in the laboratory. Mechanical disturbance of mycelia leading to released cytoplasm was necessary to allow mycovirus transfer between vegetatively incompatible strains. In contrast, heterokaryon incompatibility did not prevent mycovirus transfer between *A. nidulans* strains.

The potential of interspecies transmission of dsRNA elements has also been investigated in the laboratory and it has been successfully demonstrated between *A. niger* (as mycovirus donor) and *A. ficuum*, *A. oryzae*, *A. tubingensis*, *A. nidulans*, and in addition to the aforementioned hyphomycetes, the yeast *Saccharomyces cerevisiae* (as mycovirus recipients).

Genomes

To date, only a few mycoviruses from *Aspergilli* have had their genomes fully sequenced and annotated. These include the *A. foetidus* mycovirus complex, comprising of a member of the family *Totiviridae* and two as of yet unclassified viruses, members of the families *Chrysoviridae*, *Partitiviridae* and *Narnaviridae* and a member of the provisionally designated family *Polymycoviridae* (Fig. 1, Table 1). Families *Totiviridae*, *Chrysoviridae*, and *Partitiviridae* accommodate mycoviruses with dsRNA genomes within isometric virions composed of viral proteins. More specifically, *Chrysoviridae*, and *Partitiviridae* have four and two genomic segments, respectively, each one

Fig. 1 Schematic representation of the genomic organization of all fully sequenced *Aspergillus* mycoviruses. For each genomic segment, the ORF(s) (colored boxes) are flanked by 5'- and 3'-UTRs (black boxes) and the function of the encoded protein(s) is indicated.

Table 1 Sequence properties of known *Aspergillus* mycoviruses

Virus name	Abbreviation	Original host	Segment (bp)	ORF size (nt; aa; kDa)	UTR length (bp)	
					5'-UTR	3'-UTR
Aspergillus foetidus fast virus	AfV-FRN	<i>A. foetidus</i> IMI 41871	dsRNA 1 (3571)	3375; 1124; 127	51	145
			dsRNA 2 (2734)	2406; 801; 87	48	280
			dsRNA 3 (2418)	2181; 726; 79	50	187
			dsRNA 4 (1961)	1743; 580; 65	50	147
Aspergillus foetidus slow virus 1	AfV-S1	<i>A. foetidus</i> IMI 41871	dsRNA 1 (5194)	4745; 741/839; 78/92	373	76
Aspergillus foetidus slow virus 2	AfV-S2	<i>A. foetidus</i> IMI 41871	dsRNA 1 (3634)	2889; 962; 110	509	236

encapsidated separately, while *Totiviridae* have non-segmented genomes. In contrast, family *Narnaviridae* accommodate unencapsidated mycoviruses with ssRNA genomes.

The *Aspergillus foetidus* Mycovirus Complex

The *A. foetidus* mycovirus complex, *i.e.*, the seven dsRNA elements found in *A. foetidus* strain IMI 41871, was initially reported in the 1970s and used as a model system to study virus replication and transcription, although the actual sequence of these elements was determined in the 2010s. Its presence is widespread among *Aspergilli*, since it has been noted not only in different isolates of *A. foetidus* but also in *A. niger*. The seven dsRNA elements are accommodated in two different classes of VLPs, designated as ‘fast’ and ‘slow’ based on their electrophoretic mobility. The ‘fast’ and ‘slow’ VLPs are both isometric and similar in diameter, approximately 33–37 nm; however they are serologically unrelated to each other and antibodies specific for one class of VLPs do not cross-react with the other, suggesting that each class of VLPs is constructed with a distinct capsid protein.

The ‘fast’ VLPs accommodate a yet unclassified mycovirus with four dsRNA elements as its genome, each encapsidated separately. Each one of the four dsRNAs has a single open reading frame (ORF) flanked by conserved 5'- and 3'-untranslated regions (UTRs) and a 3' poly(A) tail. The two larger RNAs encode the RNA-dependent RNA polymerase (RdRP) and the capsid protein (CP), respectively, while the other two encode proteins of unknown function. Similar mycoviruses have been described not only in *Aspergilli* but in other ascomycetes as well, such as *Alternaria alternata* and *Fusarium poae*.

The ‘slow’ VLPs accommodate the remaining three dsRNA elements: a member of the genus *Victorivirus*, family *Totiviridae*, which has a linear non-segmented genome and encodes an RdRP and a CP; an unclassified mycovirus with a single open reading frame encoding an RdRP, closely related to viruses found in other ascomycetes, such as *Fusarium poae*, *Penicillium aurantiogriseum*, and *Rosellinia necatrix*, and in basidiomycetes, such as *Rhizoctonia solani*; and a satellite RNA, less than 0.5 kbp in size with no protein coding capacity. All three dsRNA elements depend on the victorivirus, which produces the capsid protein that forms the

'slow' VLPs, for their encapsidation. The victorivirus and the unclassified virus each encode their own RdRP for replicating their own genomes, and the RdRP of the unclassified virus is also responsible for the replication of the satellite RNA.

Partitiviruses

Three viruses belonging to the family *Partitiviridae*, genus *Gammapartitivirus*, have been found in *Aspergilli*, *Aspergillus ochraceus* virus (AoV) was isolated from *A. ochraceus*, while *Aspergillus fumigatus* partitivirus-1 (AfuPV-1) and *Aspergillus fumigatus* partitivirus-2 (AfuPV-2) were discovered in *A. fumigatus*. Notably, the two partitiviruses from *A. fumigatus* are not closely related. Each virus has two dsRNA segments as its genome, containing one ORF flanked by conserved 5'- and 3'-UTRs. As is typical for partitiviruses, the larger dsRNA encodes the RdRP and the smaller the CP. The *Aspergillus ochraceus* virus in particular has an additional component, which has been fully sequenced and is known to contain an ORF encoding a protein of unknown function. Since its UTRs are very similar to those of the other two partitivirus components, it is most likely that it is replicated by the RdRP.

Chrysovirus

The presence of a virus belonging to the genus *Alphachrysovirus*, family *Chrysoviridae* and named *Aspergillus fumigatus* chrysovirus (AfuCV) has been reported in *A. fumigatus*. The AfuCV genome consists of four dsRNAs, each one containing an ORF flanked by conserved 5'- and 3'-UTRs. The two largest dsRNAs encode the viral RdRP and CP, respectively, while the other two dsRNAs encode proteins whose function is not fully understood. More specifically, the smallest dsRNA encodes a putative cysteine protease (alphachryso-P4) while the third dsRNA encodes a protein (alphachryso-P3) that shares significant sequence similarity with the N-terminus of the RdRP. The alphachryso-P3 contains a 'phytoreo S7 domain', initially described in members of the genus *Phytoreovirus*, family *Reoviridae*, which is considered to interact with the RdRP and play a role in viral RNA binding and packaging. Furthermore, the remote protein homology detection HHpred software showed that the AfuCV alphachryso-P3 contains a P-loop NTPase domain near its N-terminus, which has homologous sequences in RdRP. Members of the P-loop NTPase domain superfamily are characterized by conserved nucleotide phosphate-binding motifs, also referred to as the Walker A motif (GxxxxGK [S/T]), and the Walker B motif (hhhh[D/E]), where h is a hydrophobic residue.

Narnaviruses and Mitoviruses

Three members of the family *Narnaviridae* have been sequenced in *A. fumigatus*, two belonging in the genus *Narnavirus* and one in the genus *Mitovirus*. These viruses encode only one protein, the RdRP responsible for replication. The two narnaviruses are not closely related and they are considered the simplest, smallest viruses. Unlike the mitovirus, which is found in mitochondria, narnaviruses are cytoplasmic. These are the only ssRNA mycoviruses reported in *Aspergillus* to date, although it is believed that the unclassified virus in the 'slow' *A. foetidus* mycovirus complex also has an ssRNA genome.

Polymycoviruses

The prototype member of the novel proposed family *Polymycoviridae*, designated as *Aspergillus fumigatus* tetramycovirus-1 (AfuTmV-1), was discovered in *A. fumigatus*. AfuTmV-1 has four dsRNA segments as its genome, similarly to members of the families *Chrysoviridae* and *Quadriviridae* and the unclassified virus in the 'fast' *A. foetidus* mycovirus complex; however, unlike these viruses, AfuTmV-1 segments are smaller in size, ranging from 1 kbp up to 2.5 kbp in length. AfuTmV-1 does not have a capsid and can be isolated from the fungus as long chains of dsRNA associated with a protein. Additionally, it was the first viral entity shown to be infectious as naked dsRNA, following introduction of its purified genome into *A. fumigatus* protoplasts. This was a paradigm-shifting discovery since, unlike the genome of positive-sense ssRNA viruses that can successfully replicate following its introduction in the host cells, dsRNA viruses were previously considered not to be infectious but as whole virions.

The largest dsRNA encodes the viral RdRP, which is related to the RNA picorna-superfamily and has two unusual characteristics that make it unique: firstly, it is evolutionary closer to members of the families *Astroviridae* and *Caliciviridae*, which have positive-sense, single-stranded RNA genomes, and infect birds and mammals; secondly, its GDD motif, responsible for the catalytic activity of the enzyme, has been replaced with GDNQ, characteristic of negative-stranded RNA viruses such as those in the order *Mononegavirales*, which include important human pathogens such as measles, rabies, and Ebola. The second largest dsRNA encodes a protein of unknown function containing a putative endoplasmic reticulum (ER) retaining signal peptide and a short trans-membrane alpha-helix together with a zinc finger-like motif similar to those that bind nucleic acids. It is hypothesized that it acts as a scaffold protein, recruiting the replication complex in the ER and facilitating the interaction among the viral RNA and the viral proteins. Both RNA and DNA viruses, such as hepatitis C and vaccinia, are known to utilize and rearrange the ER membrane for their replication and assembly and it is conceivable that polymycoviruses are also associated with this host organelle. The third

largest RNA encodes a methyl-transferase responsible for capping the positive RNA strands of the virus; a conserved catalytic motif and a FAD/NAD(P)-binding Rossmann fold domain have been identified in the protein sequence. The latter binds a coenzyme, which acts as an acceptor or a donor for the hydrogen anion lost or gained during the redox reaction catalysed by the methyl-transferase. The presence of the capping structure leads to the recognition of the viral RNAs, which act as mRNAs, by the host's ribosomes and to the translation of the viral proteins. Notably this is the first report of a capping enzyme and the RdRP being on distinct dsRNA elements. Finally, the smallest dsRNA encodes a protein hypothesized to coat the viral genome, which is non-conventionally encapsidated. This protein is enriched in the residues proline, alanine, and serine and has long intrinsically disordered regions, which may facilitate its interactions with RNA and proteins.

The aforementioned four dsRNAs and the proteins they encode are common in all known polymycoviruses; however polymycoviruses may have up to four additional genomic segments, encoding small non-homologous proteins of unknown function. It is feasible that these proteins originally participated in the formation of a capsid, since a polymycovirus from plant pathogenic fungus *Colletotrichum camelliae* has eight dsRNA segments and is encapsidated in filamentous virions. Loss of one or more of these genomic segments would not affect the ability of polymycoviruses to replicate, but would coincide with the shredding of the capsid.

Phenotypes

A. fumigatus is the major causative agent of aspergillosis and related respiratory diseases, affecting immunocompromised patients undergoing transplantation or chemotherapy and those vulnerable due to another infection, such as tuberculosis, or a genetic disorder, such as cystic fibrosis. Other *Aspergillus* species are significant food contaminants, may have industrial uses and produce toxins such as aflatoxins. A number of case studies have revealed that mycoviruses may have discernible effects on their fungal host, altering its phenotype. These comparisons typically involve virus-free and virus-infected isogenic lines; *i.e.*, the same fungal isolate with and without the virus, in order to ensure that any observed phenomena are due to the presence of the virus and not to potential differences in the genomic background of the host. The most easily detected phenotypes are alterations in pigmentation of the fungus and may be accompanied by differences in growth, conidiation, pathogenicity, and/or mycotoxin production. For instance, virus infection in an *A. niger* isolate was shown to lead to reduced growth rate and production of conidia.

Virus-mediated aflatoxin production is a very interesting phenotype associated with isolates of *A. flavus*. Aflatoxins are carcinogenic secondary metabolites produced by *A. flavus* and *A. parasiticus*, which are opportunistic plant-pathogens, and can be found on a range of agricultural crops including tree nuts, corn, peanuts, grains, and soybeans, mostly in warm and humid environments. This contamination of food resources with aflatoxins, to which the consumer that can be exposed either directly or indirectly *via* meat and dairy products, is a serious medical and economic concern, particularly in developing countries. The production of aflatoxins is down regulated in the presence of uncharacterised mycoviruses in *A. flavus* strains NRRL 5565 and NRRL 5940. Nevertheless, this correlation is not universal since mycoviruses do not appear to affect aflatoxin levels in other *A. flavus* isolates or the production of the mutagenic patulin by *A. clavatus*. No attempts were made to further characterize the mycoviruses from the NRRL 5565 and NRRL 5940 strains or to take advantage of them in order to control aflatoxin production in the field.

The most extensive phenotypic studies have been performed in *A. fumigatus* isolates: the effect of different mycoviruses on fungal growth has been investigated both in solid and in liquid culture and their effect on virulence has been assessed on mice and on larvae of the greater wax moth *Galleria mellonella*, both widely used model systems for pathogenicity studies. The *A. fumigatus* isolate harboring the chrysovirus produces darker green pigmentation than virus-free isogenic line, while the isolate with the partitivirus has lighter pigmentation. Chrysovirus and partitivirus infections both lead to the formation of aconidial sectors and significantly reduced growth in solid and in liquid culture, but no effects on fungal pathogenicity were discernible. In contrast, infection of *A. fumigatus* with polymycoviruses leads to hypervirulence, or increased pathogenicity, apparently *via* two different mechanisms: in isolate A78 harboring an uncharacterised in terms of sequence polymycovirus, hypervirulence is at least partially a result of increased growth; in Af293 isolate harboring AfuTmV-1, hypervirulence is not concomitant with enhanced growth and depends on other unidentified parameters associated with pathogenicity. For instance, AfuTmV-1 may affect the expression of genes involved in the thermotolerance of the fungus, the constitution and polysaccharide content of the fungal cell wall, together with melanin pigment production, resistance to oxidative stress and other factors that influence the interplay between the fungus and the host's immune system. The association, if any, between mycovirus infection in *A. fumigatus* and clinicopathological parameters, patient survival, and azole resistance is currently unknown.

The next major challenge in the investigations of *Aspergillus* mycoviruses is understanding the molecular mechanisms and signaling pathways mediating the aforementioned phenotypes. Due to the dsRNA nature of their genomes or their replicative forms, mycoviruses act as both triggers and targets of RNA silencing, a process leading to the degradation of viral RNA as part of the anti-viral defense of the fungal host. This phenomenon has been studied in *A. nidulans* and *A. fumigatus*, demonstrating that non-conventionally encapsidated viruses, such as polymycoviruses, and encapsidated viruses, such as chrysoviruses and partitiviruses, can be silenced, while some mycoviruses may in turn suppress RNA silencing in their fungal host. Mycovirus infection may also result in differential expression of small regulatory RNAs, suggesting a putative mechanism underpinning the observed mycovirus effects on fungal hosts.

Glossary

Alpha helix (α -helix) A common protein secondary structure that is formed when the polypeptide chains twist into a spiral.

Bottleneck An evolutionary event that drastically reduces the size of a population. It can be caused by various factors but here different cell types are the contributing factor. It lowers genetic variability in a population.

Convergent evolution The process whereby organisms not closely related, independently evolve similar traits as a result of having to adapt to similar environments or ecological niches.

Evolutionary lineage A temporal series of organisms, populations, cells, or genes connected by a continuous line of descent from the ancestor to descendant. Lineages are subsets of the evolutionary tree of life. Lineages are often determined by the techniques of molecular systematics.

Jelly roll A protein fold or supersecondary structure composed of eight beta strands arranged in two four-stranded sheets. The jelly roll is the most prevalent fold among viral capsid proteins.

Modular evolution The concept that viruses contain sets of genes or modules that have a common ancestor but may be found in different arrangements in viral genomes.

Polyphyletic A group of organisms that do not share an immediate common ancestor.

Purifying selection The selective removal of mutations or alleles that are not beneficial to an organism.

RNA silencing A sequence-specific degradation of RNA, usually triggered by double-stranded RNA. RNA silencing provides an antiviral defense response at the cellular level, and is an adaptive immune system used by plants, fungi and a few other organisms.

Vegetative Compatibility The ability of hyphae to fuse (anastomosis). Vegetative compatibility is controlled by one to several nuclear genes that limit completion of hyphal anastomosis between fungal colonies to those that belong to the same vegetative compatibility group (usually abbreviated to v-c group).

Introduction

Mycoviruses are commonly found in many taxa of fungi. These viruses lack an extracellular phase but move between hyphal cells during cell division, and naturally transmit horizontally between vegetatively compatible groups through the anastomosis (fusion of hyphae). Some mycoviruses are able to facilitate anastomosis between vegetatively incompatible fungal strains by overcoming non-self recognition, a common phenomenon in fungi that enables distinction of oneself from another fungus. The non-self recognition is activated in fungi when two vegetatively incompatible hyphae come into contact resulting in compartmentalization followed by programmed cell death to interrupt the fusion between hyphae. In many systems vertical transmission of mycoviruses occurs efficiently through fungal asexual spores. The effective horizontal and vertical transmissions in mycoviruses are responsible for their widespread dispersal.

The International Committee for the Taxonomy of Viruses (ICTV) in 2017 reported twelve classified and seven unclassified families of mycoviruses. A majority of mycoviruses have double-stranded (dsRNA) genomes, but this could be partially due to bias in the analysis that often involves isolation of dsRNA as a starting point. Unlike most of the single-stranded (ss) RNA families, the extremely broad range of the dsRNA viruses in fungi appears rather unusual. The three largest families of dsRNA viruses, *Partitiviridae*, *Totiviridae*, and *Reoviridae*, show broad host ranges, infecting two or three kingdoms of eukaryotic hosts, implying ancient origins.

In general, RNA viruses have higher evolutionary rates because the RNA dependent RNA polymerases (RdRps) that replicate their genomes are more error-prone than those for DNA dependent DNA polymerase. The estimated rate of nucleotide substitutions per site per year for animal RNA viruses falls within one order of magnitude of 1×10^{-3} . No parallel studies on mycovirus evolutionary rates are reported. However, unlike most animal RNA viruses, mycoviruses have an exclusively intracellular lifestyle that predominantly limits them to infection of a single fungal host, or to vegetatively compatible populations. Moreover, mycoviruses experience bottlenecks within their hosts. In many fungi such as the genus *Aspergillus*, mycoviruses are transmitted vertically via asexual spores but not through sexual spores. Mutation events in mycoviruses with dsRNA genomes are further constrained by their stamping-machine mode of replication. In stamping-machine replication, one strand of the genome produces multiple copies, but this is then copied only once to produce the genomic RNA. In most ssRNA viruses each strand can be amplified during replication, resulting in a logarithmic increase in progeny strands, and allowing for a higher probability of mutation events to occur. It is likely that such a lifestyle of mycoviruses results in a lower tolerance for mutations, or a higher pressure of purifying selection and hence a lower evolutionary rate over time. Studies in plant persistent viruses that share a similar lifestyle with mycoviruses and belong to the families common to both fungal and plant viruses, show similar slow rates of evolution. For example, an endornavirus that infects the ancestor of domesticated rice and a related virus that infects cultivated rice have diverged by about 24% over the 10,000 years since rice was first cultivated. Another example is a chrysovirus isolated from

ancient maize cobs from about 1000 years ago that can still be found in modern maize. The virus sequences have diverged by only about 3%.

Due to the lack of an extracellular phase for mycoviruses, and dependence on the host for transmission, mycoviruses are generally thought to have co-evolved with their hosts. Their symptomless and persistent infections and, in some cases positive interactions with hosts, support this view. However, phylogenetic studies show mycoviruses are diverse despite sharing the same lifestyle and do not seem to have evolved from a single ancestral virus.

Evolutionary History and Drivers of Evolution

A wide range of evolutionary forces contributes to genetic variability and adaptability of mycoviruses to a changing environment. A comprehensive evolutionary study across the mycoviruses is lacking, however, findings from some mycovirus taxa (e.g., families) and individual species provide us a picture of evolutionary forces shaping the extant population. The family *Totiviridae* contains mycoviruses with undivided dsRNA genomes and is one of the more studied families of mycoviruses. Some members of this family also infect protozoans. Sequence comparisons of predicted RdRp amino acids among members show significant sequence similarity with eight conserved motifs among totiviruses that infect yeast, smut, filamentous fungi, and protozoans. However, the similarity in coat proteins (CPs) among members is not as pronounced as with the RdRps, a common observation among viruses. Two evolutionary lineages are distinct among totiviruses infecting fungi. One of the lineages, now grouped under the genus *Victorivirus* differs from the other (grouped under the genus *Totivirus*) by its RdRp expression strategy. In *Victorivirus* the RdRp open reading frame is separate from that of the CP, whereas these reading frames are fused in members of the *Totivirus* and are expressed by a frame-shifting mechanism. The ancestral relationships of the totiviruses infecting fungi are uncertain. However, the genus *Victorivirus* is phylogenetically closer to the totiviruses infecting protozoans than the totiviruses of yeast and smut fungi indicating that the fungal viruses in the family *Totiviridae* are probably polyphyletic.

Partitiviruses infecting fungi are another widely studied group of viruses. The viruses in the family *Partitiviridae* infect fungi, plants, and oomycetes and possess two dsRNAs genome segments. The members of *Partitiviridae* infecting fungi have three distinct lineages, out of which only one lineage includes exclusively fungi (filamentous, ascomycetes: *Gammapartitivirus*) as hosts, while the two other lineages have both fungal and plant hosts (*Alphapartitivirus* and *Betapartitivirus*). The lineages of partitiviruses with both fungal and plant hosts suggest a horizontal transfer of members between kingdoms.

An analysis of the protein domains of endornaviruses infecting fungi indicates diverse origins suggesting a modular evolutionary history. The endornaviruses infecting fungi have naked ssRNA genomes that encode polyproteins for various function. The helicase domains of *Gremmeniella abietina* type B RNA virus XL1 and *Chalara elegans* endornavirus 1 (CeEV1) are derived from two different protein superfamilies. Similarly, *Helicobasidium mompa* endornavirus 1 and CeEV1 have glycosyltransferase domains originating from the different protein family roots. The occurrence of domains with similar functions but of different origins in different fungal endornaviruses indicates a modular convergent evolutionary strategy. In fact, the evolution of domains of similar function but highly divergent primary sequence in many mycoviruses is sometimes interpreted as ancient divergence, but can equally be understood as convergent evolution.

The highly conserved RdRp domain in endornaviruses is related to the RdRp of closteroviruses, which are plant ssRNA viruses. A phylogenetic analysis of hypovirus RdRps and the gain or loss of other genes support the hypothesis that these naked (+) ssRNA fungal viruses are derived from the potyviruses, another group of plant (+) ssRNA viruses. The mitoviruses, found in the mitochondria of fungi, may have originated from bacteriophages in the *Leviviridae* family, the only (+) ssRNA family in prokaryotes. It seems likely that the mitoviruses evolved from a bacterial virus that lost its coat protein and other genes. The related narnaviruses infecting yeasts are found in the cytoplasm, and could have originated from a mitovirus that escaped to the cytosol. The origin of dsRNA viruses is unclear, but one possibility is that a (+) ssRNA could have been the ancestor of all dsRNA viruses that encapsidated a replicative form (dsRNA) together with the RdRp. Mitoviruses, hypoviruses, and endornaviruses, that have a ssRNA-like RdRp, but are found as unencapsidated dsRNA replicative forms, could be evolutionary intermediates in this process.

The major evolutionary forces affecting more recent evolution of the mycoviruses are mutation and selective sweeps that were discussed above with respect to the different lineages in many groups of mycoviruses. Besides mutation, recombination and horizontal gene transfer (HGT) have been reported often in the literature. Recombination is an evolutionary force that is common in some ssRNA viruses. Recombination occurs when an RdRp switches its template from one molecule to another during virus replication. Since dsRNA viruses replicate exclusively within the virus particle, the opportunity for recombination between templates is probably very uncommon. However, a low frequency of recombination events is reported in *Ustilago maydis* virus H1, a member of the genus *Totivirus*. In members of hypoviruses such as *Cryphonectria hypovirus* 1 (CHV1) that replicate as ssRNA viruses homologous recombination events are noted frequently and some of the recombinant lineages appear to be responsible for the spread of the virus in Europe.

Recent studies suggest that HGT between diverse mycoviruses as an important force contributing to evolution. The homologs of the S7 protein domain, a DNA-binding protein common in phytoreoviruses in the family *Reoviridae*, are reported from many mycoviruses that belong to the families *Endornaviridae*, *Totiviridae*, *Chrysoviridae*, and unclassified monopartite dsRNA fungal viruses. The domain is associated with the RdRp in many chrysoviruses but found with CPs and polyproteins in totiviruses and endornaviruses, respectively. Phylogenetic analysis of the S7 domains from various mycoviruses supports HGT across species. HGT is also reported in *Sclerotinia sclerotiorum* reovirus 1 (SsReV1), a member of the family *Reoviridae*. Virus protein 6 and virus protein 7 of *Sclerotinia sclerotiorum* reovirus 1 (SsReV1) have sequence similarities with dsRNA binding motif (dsRBM) and

reovirus sigma C protein (Reo_ σ C), respectively. Reoviruses can infect mammals, protozoans, insects, plants, and fungi. Homologs of the dsRBM and Reo_ σ C are found in many reoviruses and diverse virus lineages outside the family *Reoviridae*. The phylogeny based on dsRBM and Reo_ σ C sequences supports HGT.

Effects of Host Divergence in the Evolution

The complex relationship between viruses and their hosts can result from any evolutionary event such as adaptation to the hosts. But the question is “How much of the diversification of mycoviruses is linked to the diversification of their fungal hosts?” In one study of mycovirus-host codivergence, results indicated codivergence as a dominant mode of virus diversification in *Partitiviridae* and *Totiviridae*, but not in other mycovirus families. However, the lack of codivergence in other families might be the result of insufficient sampling.

As viruses employ host translation systems, their proteins use the same genetic code as their host organism. There are a few organisms that use modified genetic codes rather than the universal genetic code. If a virus that uses the universal genetic code infects a host that utilizes an alternative genetic code, this would constitute high fitness costs. These differences in genetic codes could inhibit viral jumping between different hosts. Some authors have hypothesized that alternative genetic codes could be used as an antiviral strategy against virus transfers from other hosts. The effects of genetic code shifts on virus-host co-evolution remain poorly understood.

Mitoviruses (family *Narnaviridae*) have the simplest genome among mycoviruses. They are capsid-less ssRNA viruses that encode only an RdRp. While all other known mycoviruses reproduce in the fungal cytoplasm, mitoviruses are unique in reproducing in the mitochondria. Fungal mitochondria often use an alternative genetic code, in which the universal stop codon UGA encodes tryptophan (Trp). Mitoviral RdRps have internal UGA codons, so as these RdRps are active in mitochondria, then UGA also encodes Trp in mitoviruses.

Recently mitovirus-like sequences have been found in plant mitochondria and also integrated into the nuclear genome of many vascular plants. The latter are not transcriptionally active. The plant mitoviruses do not contain the UGA codon for Trp, so they have adapted to this host change. Although, in most fungal mitochondria UGA (Trp) is a common codon, in some fungi UGA (Trp) is a rare mitochondrial codon, and in mitoviruses in these hosts the UGA is mostly absent. Thus, fungal mitoviruses are adapted to their host species by using UGA as Trp codon, but this changes with host species. Recent investigation of plant transcriptomes revealed the presence of many complete genomes of plant mitoviruses, providing strong evidence for genuine plant mitoviruses.

In a study on *Scheffersomyces segobiensis*, a fungus with an alternative genetic code where CUG codes for serine instead of leucine, a dsRNA virus of the genus *Totivirus* has removed all but one of the CUG codons from functional positions of its genome, presumably for adaptation to the host modified genetic code. Without this shift in the genetic code, protein folding would be impacted by replacing a hydrophobic residue with a polar residue.

Based on phylogenetic analysis, *Scheffersomyces segobiensis* virus L evolved from exogenous totiviruses with a standard genetic code. Apparently, genetic code shifts are not serious barriers against virus jumping between different hosts.

Coinfection and Evolution

Coinfection of multiple mycoviruses is common in nature. Coinfecting mycoviruses impose pressure on each other resulting in neutral, synergistic or antagonistic interactions. In many cases, mycoviruses transfer across different fungal strains of vegetative incompatibility by overcoming non-self recognition. However, some mycoviruses can suppress the non-self recognition and facilitate the exchange of mycoviruses from diverse vegetatively incompatible groups. This opens up the opportunity for interactions among different mycoviruses while coinfecting the same host that have evolutionary consequences. One example is the interactions between Mycoreovirus 1 (MyRV1) from the genus *Mycoreovirus* and CHV1 from the genus *Hypovirus*, in the chestnut blight fungus, *Cryphonectria parasitica*. MyRV1 possesses 11 dsRNA segments (S1-S11). The multifunctional protein p29, encoded by CHV1 induces reproducible intragenic rearrangements of the S6 and S10 genomic segments of MyRV1, including duplication in S6 and an internal deletion in S10. Further, p29 copurifies with MyRV1 genomic RNA and binds in vitro to the VP9 protein of MyRV1 that is involved in replication.

Fungi use the adaptive immune system of RNA silencing to counteract RNA viruses. RNA silencing may also contribute to viral RNA recombination. In coinfection, it is likely that RNA silencing may lead to the production of chimeric viral RNAs as a product of intermolecular recombination. Such possibilities have evolutionary consequences and deserve further investigations.

Structural Evolution of Mycoviruses

The origin of the RdRp of RNA viruses is unclear. The protein sequences of RdRps, as hallmark genes in RNA viruses, are divergent, but contain well-conserved domains. The high level of structural similarity based on atomic structure among RdRps of all groups of RNA viruses [dsRNA, (+) ssRNA, and (-) ssRNA] also could imply a common origin for all RdRps. However, it is not possible to be certain whether these critical molecules have diverged or converged for a common function, and if they have diverged, it is difficult to be certain which extant form of RdRp is closest to the ancestral state.

The virion architecture is also a crucial element in understanding virus origins. In spite of tremendous genetic variation, there are a limited number of capsid protein folds, and only a small subset of these have the potential to result in a virus particle.

However, the origin of viral capsids is a poorly understood aspect of virus evolution. Unlike the RdRps, the capsid proteins have no conserved domains, and primary protein sequence analysis, even in viruses in the same family, indicates a polyphyletic origin of these genes. This type of chimeric origin is a common evolutionary scenario for encapsidated mycoviruses.

Recent analyses of virion structure have revealed unexpected similarities in the folds of capsid proteins among these different viruses, suggesting an evolutionary connection among viruses that infect hosts residing in different kingdoms of life. Two different evolutionary trajectories could be concluded from such observations, divergent or convergent evolution. In the divergent scenario, there is a common ancestor for each separate lineage that existed before their host organisms diverged, but these proteins have diverged beyond any recognition at the sequence level. The other scenario would be that the structural similarities are because of convergent evolution to solve the problem of making a stable and viable capsid.

A comparative analysis to investigate the diversity and potential origins of viral capsids resulted in 18 “structure-based viral lineages”, in which 76.3% of viral taxa with defined folds of the major capsid proteins could be categorized. One of these lineages is the dsRNA bluetongue virus (BTV)-like viruses. BTV is a member of the *Reoviridae*.

The icosahedral mycoviruses in the *Totiviridae*, *Partitiviridae*, *Megabirnaviridae*, *Chrysoviridae*, and *Quadriviridae* families have a unique 120-subunit $T = 1$ jelly-roll capsids that also have been described as the internal shell in bacteriophages of the family *Cystoviridae* and members of *Reoviridae*, and as viral capsids in picobirnaviruses, which infect higher eukaryotes. They share a structural signature with the lineage of the dsRNA BTV-like viruses. Reoviruses form a complex capsid consisting of two icosahedral shells similar to cystoviruses, indicating a possible evolutionary relationship between these families.

The icosahedral capsid of dsRNA viruses remains intact during transcription, extruding the ssRNAs that act as mRNAs and as pregenomic RNAs from the intact capsids, probably to avoid triggering host defense mechanisms. To date, four $T = 1$ capsids of mycoviruses have been resolved at the atomic level: *Saccharomyces cerevisiae* 1-A virus (*Totiviridae*), *Penicillium chrysogenum* virus (*Chrysoviridae*), *Penicillium stoloniferum* virus F (*Partitiviridae*), and *Rosellinia necatrix* quadrivirus 1 (*Quadriviridae*). The amino acid sequences of the above four capsid proteins are quite different, however, they all have the same fold, predominantly α -helical, which is also a hallmark of BTV lineage. According to phylogenetic analyses of the RdRps of partitiviruses, they share a common ancestor and RdRp has monophyletic origin in this group of viruses, however, despite the striking similarity of their structure, coat protein genes are often unrelated and are clearly polyphyletic. So, in this case, the evolution of the RdRp alone does not reflect the evolution of partitiviruses, and it is likely that partitiviruses gained coat protein genes at different times, from various sources. All partitiviruses with resolved atomic structures, despite their high coat protein sequence divergence, share distinctive features including surface arches that are unique among dsRNA viruses infecting fungi and not seen in other mycovirus families. The presence of surface arches in partitiviruses, with thin capsid shells, may have a role in stabilization of the capsid, however, their main function is still unknown.

Among dsRNA viruses, partitiviruses and picobirnaviruses, have minimalist genomes consisting of two dsRNA segments, and share capsid structure and distinctive features. However, picobirnaviruses, as vertebrate viruses, are grouped in a different family due to a variety of differences from partitiviruses including host range. Given the structural similarity, two different evolutionary trajectories are suggested for *Partitiviridae* and *Picobirnaviridae* capsids, either they are diverged from a common ancestor that existed before their host organisms diverged or they are converged from different ancestors as a solution to the problem of a thin, unstable capsid protein.

Obviously, not only evolution of the RdRp but also evolution of other genes either gained or lost during evolution are important in the evolution of mycoviruses. There is much to still be learned about mycovirus evolution, largely because this group of viruses is very understudied, and most of the work done has centered on viruses of fungi that are pathogenic in plants or animals.

Glossary

Hypovirulence Reduced virulence of phytopathogenic fungi upon mycovirus infections.

Mycovirus Virus that can replicate and proliferate in fungal cells.

Virocontrol Biological control with hypovirulence-associated mycovirus.

Introduction

All living beings, as well as human beings, can be infected by innumerable viruses. As an important component of virosphere, mycoviruses (or fungal viruses) infect and replicate in fungi, and maybe play important roles in shaping fungal ecosystem under nature. Hypovirulence is a phenomenon that phytopathogenic fungi infected by one or more mycoviruses have reduced or lose virulence on their hosts. Hypovirulence-associated mycoviruses isolated from nature have potential to prevent and control crop fungal diseases, and it is also a useful exploration to open up a new strategy for the management of plant diseases. Hypovirulence-inducing *Cryphonectria hypovirus 1* (CHV1) has been successfully utilized to effectively control chestnut blight disease in Europe, which is a classic virocontrol example of fungal disease and also attracted more phytopathologists to unearthed mycovirus resources. Mycoviruses have been discovered in all major fungal groups during more than 50-year research, and mixed infections with multiple related or unrelated mycoviruses have frequently been confirmed in a single fungal isolate. For example, *Ophiostoma novo-ulmi* Log1/3–8d2 (Ld) with diseased phenotype was reported to be infected with twelve distinct mitoviruses. Two unrelated RNA viruses, yado-nushi virus 1 and yado-kari virus 1, co-infect a single isolate of phytopathogenic fungus *Rosellinia necatrix*, and potentially interplay in vivo. The advanced technique of high-throughput sequencing further supplies new insight into the complexity of the mixed infections in fungi. A hypovirulent strain DC17 of *Rhizoctonia solani* (AG2–2-IV) harbors 17 different mycoviruses that represent different virus lineages. Sixteen mycoviruses occur in a single strain of *Fusarium poae*. Those reports revealed that the mixed infections in fungi are fairly common and more complex than we previously thought.

Sclerotinia sclerotiorum (Lib.) de Bary is a ubiquitous necrotrophic pathogen and has a remarkably broad host range, encompassing over 400 species including important economic crops canola (oilseed rape), soybean, sunflower, and vegetables. In the later stage of the disease, *S. sclerotiorum* usually produces sclerotia, the resting structure for over-winter and summer, to survive for several years in soil. Under congenial conditions (such as moist soil, 10–20°C temperature), sclerotia germinate to produce apothecia (carpogenic germination) or directly produce mycelia (myceliogenic germination), and then results in damage of the plant tissue via the sophisticated pathogenicity mechanism. The disease caused by *S. sclerotiorum* is responsible for yearly several 100 millions of US dollars crop losses worldwide. To effectively control the sclerotinia disease, fungicides have been continuously used widely. However, long term dependence on chemical pesticides for sclerotinia disease leads to the pollution of agricultural environment and ecological damage, which threatens food safety and human health. Therefore, environment-friendly biological control (such as virocontrol) for crop diseases is an alternative strategy for the sustainable development of agriculture.

The first description of hypovirulence and dsRNA elements in *S. sclerotiorum* was published on Canadian Journal of Plant Pathology in 1992. So far, diverse mycoviruses with RNA or DNA genomes have been discovered in *S. sclerotiorum* (Table 1) as well as a DNA mycovirus, *Sclerotinia sclerotiorum* hypovirulence-associated DNA virus 1 (SsHADV1) and the firstly identified negative RNA mycovirus, *Sclerotinia sclerotiorum* negative-sense RNA virus 1 (SsNSRV-1). By application of a high-throughput sequencing-based metatranscriptomic approach, 84 Australian *S. sclerotiorum* isolates were identified to host 57 mycoviruses assigned into 10 distinct viral lineages, and 28 mycoviruses were detected from American *S. sclerotiorum* strains, suggesting that mycovirus infections are quite common in *S. sclerotiorum* population. Herein, we summarized the genomes of mycoviruses identified and molecularly characterized from the reported twenty-three *S. sclerotiorum* strains (Table 1). Some of those identified mycoviruses could confer hypovirulence, and are potential resources for biological control of Sclerotinia disease. For example, SsHADV1, the first example of extracellular transmission, has the potential to develop a virocontrol agent (or viral fungicide), and has been confirmed to be effectively control rapeseed rot disease development under field conditions. In addition, SsHADV1 can convert lifestyle of *S. sclerotiorum* from pathogenic fungus to beneficial endophyte, which enhance rapeseed resistance and yield. Notably, more than 80% (19/23) of those identified strains are mix-infected by multiple related or/and distinct mycoviruses (Table 1). In this article, we focus on characteristics of mixed infections of mycoviruses and their impacting in the individual strains of *S. sclerotiorum*, and also will discuss their potential interactions among viruses or their interactions with *S. sclerotiorum*.

Table 1 Mycoviruses infecting strains of *Sclerotinia sclerotiorum*

Strains	Mycoviruses ^a	Type of genome	Phenotype
Ep-1PN	SsDRV, SsRV-L	+ ssRNA	Hypovirulence
DT-8	SsDAHV1	ssDNA	Hypovirulence
Sunf-M	SsPV-S, SsNsRV-1	dsRNA, + ssRNA	Virulence
SZ-150	SsHV1, SsBV3, SsMTV1	dsRNA, + ssRNA	Hypovirulence
KL-1	SsMV1, SsMV2	+ ssRNA	Hypovirulence

^aAbbreviated mycovirus names: SsDRV, Sclerotinia debilitation-associated RNA virus; SsRV-L, Sclerotinia sclerotiorum RNA virus L; SsDAHV1, Sclerotinia sclerotiorum hypovirulence associated DNA virus 1; SsPV, Sclerotinia sclerotiorum partitivirus; SsNsRV-1, Sclerotinia sclerotiorum negative single RNA virus 1; SsHV, Sclerotinia sclerotiorum hypovirus; SsBV, Sclerotinia sclerotiorum botybirnavirus; SsMTV1, Sclerotinia sclerotiorum mycotymovirus 1; SsMV, Sclerotinia sclerotiorum mitovirus; RcEV1, Rhizoctonia cerealis endornavirus 1; SsReV1, Sclerotinia sclerotiorum reovirus 1; SsYkV1, Sclerotinia sclerotiorum yadokarivirus 1; SsFV1, Sclerotinia sclerotiorum fusarivirus 1; SsMBV1, Sclerotinia sclerotiorum megabimavirus 1; SsDFV, Sclerotinia sclerotiorum deltaflexivirus; BpRV1, Botrytis porri RNA virus 1; HuSRV1, Hubei sclerotinia RNA virus 1; SsMyRV4, Sclerotinia sclerotiorum mycoreovirus 4.

Strain Ep-1PN Harbors Two Positive-Single Stranded RNA Mycoviruses

Strain Ep-1PN was originally isolated from a sclerotium collected from a diseased eggplant (*Solanum melongena*) and had lower virulence on rapeseed plants. dsRNA extraction suggested that Ep-1PN contained at least three extra-chromosome dsRNA segments (L, M, and S) with 7.4 kbp (base pairs), 6.4 kb, and 1.0 kbp in size, respectively. Subsequently, the L segment was confirmed to be the genome of Sclerotinia sclerotiorum RNA virus L (SsRV-L), M segment represented the replicative form of the genome of Sclerotinia sclerotiorum debilitation-associated RNA virus (SsDRV), and segment S was a defective RNA derived from SsDRV.

SsDRV is the first molecularly characterized mycovirus based on the full-length genome in *S. sclerotiorum*. SsDRV contains 5419 nucleotides (nt) excluding the poly (A) tail and has a single open reading frame (ORF). This ORF encodes a polyprotein with three conserved domains of methyltransferase, helicase and RNA-dependent RNA polymerase (RdRp). In *S. sclerotiorum* strain SX247 (see strain SX247 section), another strain SsDRV/SX247 was characterized, and share high sequence identity (81%) with SsDRV from strain Ep-1PN. Based on the phylogenetic analysis, SsDRV, the exemplar virus of the species *Sclerotinia sclerotiorum debilitation-associated RNA virus* of the genus *Sclerodarnavirus*, is closely related to the replicases of potex-like plant viruses (potexviruses) and Botrytis virus F (BVF) within the family *Alphaflexiviridae*. Interestingly, SsDRV has a single gene but lacks a coat protein gene, which is significantly distinct from other members of *Alphaflexiviridae* that usually contains five or six genes, and one of them encodes coat protein.

The genome of SsRV-L is 6043 nt in length, with a poly (A) tail. Similar to SsDRV, SsRV-L has only one reading frame and encodes a polyprotein (viral replicase). There is a significant sequence similarity between SsRV-L and human hepatitis E virus (HEV) replicase, which is the first discovery of mycovirus related to the human virus. Phylogenetic analysis showed that SsRV-L was closely related to members from *Rubi-like virus*, *Closterovirus*, *Benyvirus*, *Tobamovirus* and *Omegatetravirus*. Six mycoviruses closely related to SsRV-L have been recently detected in two phytopathogenic fungi *Rhizoctonia solani* (three mycoviruses) and *Sclerotium rolfii* (three mycoviruses), suggesting SsRV-L and its related mycoviruses are common in fungi.

SsDRV was associated with the hypovirulence phenotype of strain Ep-1PN, while SsRV-L has a limited impact on the biological features of *S. sclerotiorum*. Thus, the interaction system of *S. sclerotiorum*-SsDRV helps us to explore the possible mechanisms underlying fungal pathogenicity. 150 genes of *S. sclerotiorum* are down-regulated upon mycovirus infections. One of those genes, *Sclerotinia sclerotiorum integrin-like gene* (SSITL), encodes a secreted protein and is related to the virulence of *S. sclerotiorum*. This protein was confirmed to be secreted into plant cell, and play significant role in the suppression of jasmonic/ethylene (JA/ET) signal pathway mediated resistance via direct interaction with a chloroplast protein at the early stage of infection.

Strain SX247 is Co-Infected With Two + ssRNA Mycoviruses

Strain SX247 has abnormal colony morphology on the PDA medium and is incapable of causing diseased lesions on the rapeseed. Two dsRNA segments, the replicated forms of *Sclerotinia sclerotiorum* hypovirus 2 (SsHV2/SX247) and SsDRV/SX247 (see strain Ep-1PN), were detected and determined in strain SX247. The full-length cDNA of SsHV2/SX247 is 15219 nt excluding poly (A) and contains a large ORF that encoded a putative polyprotein with three conserved domains of papain-like protease, RdRp, and viral RNA helicase. The phylogenetic analysis revealed that SsHV2/SX247 forms an independent phylogenetic branch with hypovirus infecting *Sclerotium rolfsii*. Two other strains (SsHV2/5472 and SsHV2L) of SsHV2, respectively, were molecularly characterized from New Zealand isolate 5472 and American isolate 328 (co-infection with a strain of *Sclerotinia sclerotiorum* endornavirus 1). Compared to SsHV2/SX274 and SsHV2/5472 that are basically all the same in the genomic organization, SsHV2L lacks a fragment of 1.2 kb near the 5' terminus and has an insertion of 524 nt related to *Valsa ceratosperma* hypovirus 1 (NC_017099), suggesting SsHV2L is a recombinant of hypoviruses. In addition, the infectious clone of SsHV2L was successfully established to explore the interactions with *S. sclerotiorum* at the molecular level. All three strains of SsHV2 were directly or indirectly confirmed to be responsible for hypovirulence on *S. sclerotiorum* via methods of transfection with transcripts or horizontal transmission.

Strain AH98 is a Mix-Infection by Two Unrelated Single-Stranded RNA Mycoviruses

Two mycoviruses, *Sclerotinia sclerotiorum* hypovirus 1 (SsHV1) and *Sclerotinia sclerotiorum* negative-sense RNA virus 1 (SsNSRV-1), were identified from a hypovirulent strain AH98. SsHV1 and its biological features will be described in strain SZ-150 (see below). The full-length genome of SsNSRV-1, the first-ssRNA virus infecting fungi, was 10002 nt (KJ186782) with 6 non-overlapped genes (ORF I-VI) which were linearly arranged in the genome. ORF V encodes a large protein (L protein) with 1934 amino acids and is comprised of the conserved mononegaviral RdRp domain that was closely related to mononegaviruses, while other ORFs encode putative proteins with unknown function. The Gene-junction sequence of (A/U)(U/A/C)UAAU(U/A)AA(U/G)AAAACUUAGG(A/U)(G/U) that is widely present and the unique property in mononegaviruses is found at each ORF junction of SsNSRV-1. The sequence "AAAACUUAGG" serves as the transcriptional stop signal of the upstream ORF, while "UAUUUAAUAAAACU" is the transcriptional start signal of the downstream ORF. All six ORFs can be transcribed independently. In addition, ORF V and ORF VI are co-transcribed. The nucleocapsids of SsNSRV-1 are 22 nm in diameter and 200–2000 nm in length. SsNSRV-1 has defective RNAs with different internal deletions of ORF I and ORF II, and with deletions of the 5' termini. Although SsNSRV-1 is a member of *Mononegavirales*, it is different from reported members in genome organization, therefore a new family *Mymonaviridae* and genus *Sclerotimonavirus* being established to accommodate SsNSRV-1 and its related viruses. Moreover, SsNSRV-1 is widely distributed in the natural environment and has been detected in *S. sclerotiorum* strains collected from China, Australia, and USA. Transfection with SsNSRV-1 virions demonstrated that SsNSRV-1 is the key factor for hypovirulence in strain AH98.

The Hypovirulent Strain SZ-150 Contains Three Mycoviruses and a Satellite RNA

Strain SZ-150 was collected in Suizhou County of China, and its virulence on rapeseed plants was severely declined upon mycovirus infection. Application of the conventional method of dsRNA extraction, SZ-150 was originally considered to harbor two mycovirus-related elements, SsHV1 and a co-replicating satellite RNA (SatH). The genome of SsHV1 is 10,398 bp, excluding a poly (A) tail. SsHV1 contains a single ORF encoding a polyprotein with three conserved domains of glycosyltransferase, RdRp, and viral helicase. SsHV1 is phylogenetically related to hypoviruses, and is the first identified hypovirus in fungi other than *Cryphonectria parasitica*. SsHV1 was also detected in two *S. sclerotiorum* strains including strain AH98 coinfecting with SsNSRV-1 and the strain AX19, as well as in strains from Australia. SatH consists of 3643 nt and has an ORF encoding a putative protein (p70) with unknown biological functions. SatH replication is entirely dependent on the replication of SsHV1 which acts as a classic helper virus, and the genome size of SatH is larger than the previously reported viral satellite RNAs. Neither SsHV1 without SatH nor infectious cDNA of SatH without SsHV1 results in hypovirulence on *S. sclerotiorum*, suggesting SsHV1 and SatH are the co-determinant factors in eliciting hypovirulence in strain SZ-150. Further research suggested that the p70 protein encoded by SatH may play an important role as an RNA silencing suppressor to boost expression of SsHV1. It is possible that p70 may suppress the host antiviral response resulting in increased replication of SsHV1 and also guaranteeing the survival of SatH in *S. sclerotiorum*.

In addition to SsHV1 and SatH, SZ-150 was confirmed to harbor the other two mycoviruses, *Sclerotinia sclerotiorum* botybirnavirus 3 (SsBV3/SZ-150) and *Sclerotinia sclerotiorum* mycotymovirus 1 (SsMTV1/SZ-150), by the deep-sequencing of small RNAs. SsBV3/SZ-150 was assumed to be a strain of BpBV1, because of the whole genome of SsBV3/SZ-150 shares more than 95% sequence identity with *Botrytis porri* botybirnavirus 1 (BpBV1) at the nucleotide or amino acid level. SsMTV1/SZ-150 was predicted to contain a large ORF that encodes a putative replication-associated polyprotein. SsMTV1/SZ-150 is related, albeit distantly, to members of the family *Tymoviridae*. Both SsMTV1/SZ-150 and SsBV3/SZ-150 have limited contribution to hypovirulence of strain SZ-150.

Four Mycoviruses Co-Infect a Hypovirulent Strain SCH941

Two novel dsRNA viruses were identified from strain SCH941, a hypovirulent strain of *S. sclerotiorum*. One was a bipartite dsRNA virus named *Sclerotinia sclerotiorum botybirnavirus 1* (SsBV1) and the other was a novel reovirus named as *Sclerotinia sclerotiorum reovirus 1* (SsReV1). SsBV1 comprised two dsRNA segments (dsRNA1 and dsRNA2) and its genome size is 12,422 bp in total. A satellite-like RNA (SatlRNA) of SsBV1 was also found with 1647 bp. SsBV1 had spherical virions with 38 nm in diameter. SsBV1 phylogenetically clustered with BpBV1, a bipartite virus infecting *Botyis porri*, and belongs to the genus *Botybirnavirus*. Compared to the virus-free strain of *S. sclerotiorum*, infection of SsBV1 alone has no significant impacts on biological features of *S. sclerotiorum*, but SsBV1 co-infection with SatlRNA leads to slightly reduced virulence of *S. sclerotiorum*. Besides SsBV1, botybirnaviruses were isolated from *S. sclerotiorum* strain AH16 (co-infection by SsBV2 and a mitovirus) and strain SZ-150 (SsBV3) as well as from Australia strains. SsBV2 is responsible for hypovirulence, whereas SsBV3 shows asymptomatic infection in *S. sclerotiorum* (Ran *et al.*, 2016; Wang *et al.*, 2019).

SsReV1 with spherical virions (approximately 65 nm in diameter) encompasses 11 dsRNA segments (dsRNA1-dsRNA11) and its whole genome is 28,055 bp in length. The conserved 5'-terminal sequences 5'-GAGWUKK-3' (W, U or A; K, U or G) and 3'-terminal sequences 5'-UGCAGUC-3' are found in each dsRNA segment. There is only one ORF in each dsRNA segment excepting dsRNA6 and dsRNA11 in which there were two ORFs. dsRNA1 encoded protein VP1 was predicted to be the RdRp of SsReV1 responsible for virus replication. dsRNA2 encoded protein VP2 is likely to be viral methyltransferase, and dsRNA8 encoded VP8 is likely to be viral kinase and helicase. The biological functions of other proteins from SsReV1 are still unknown. Interestingly, two conserved domains, double-stranded RNA binding motif (dsRBM, Pfam 00035) and reovirus sigma C capsid protein (Reo_σC, pfam04582), were identified in the genome of SsReV1. Polygenetic analysis and multiply alignment indicate that reoviruses indeed have HGT events with other virus lineages, even with cellular organisms on a large scale. SsReV1 has a closer relationship to mammalian coltivirus than to fungal mycoreoviruses. However, dsRNA profile of SsReV1 genome was distinct from those of members within the genera *Coltivirus* and *Mycoreovirus*, suggesting SsReV1 represents a novel genus in the family *Reoviridae*. Reoviruses were reported in *C. parasitica* (MyRV1 and MyRV2), *R. necatrix* (RnMyRV3), and as well in *S. sclerotiorum* (SsMyRV4). The infections by those mycoreoviruses result in virulence debilitation of their hosts, but the *S. sclerotiorum* strain infected by SsReV1 alone shows no symptoms.

Co-infection of strain SCH941 by SsReV1 and SsBV1 failed to cause the typical lesion on rapeseed plant, but infection of a *S. sclerotiorum* strain by SsReV1-alone or SsBV1-alone showed strong virulence on the host. To eliminate the possibility of infection of strain SCH941 by other viruses overlooked by dsRNA extraction, metatranscriptomic analyzes of strain SCH941 was conducted, and finally found three new mycoviruses, *Sclerotinia sclerotiorum yadokarivirus 1* (SsYkV1), *Sclerotinia sclerotiorum deltaflexivirus 1* (SsDFV1), and SsDFV3 coinfecting the strain SCH941 (unpublished data). As a matter of fact, SCH941 was coinfecting with five mycoviruses including two dsRNA mycoviruses and three + ssRNA mycoviruses. Notably, SsBV1 and SsYkV1 always co-exist in a single isolate and SsYkV1 failed to separate from SsBV1, suggesting they could have potential interplay each other. We recently confirmed that neither SsDFV1 nor SsDFV3 is associated with hypovirulence, but hypovirulent phenotypes of *S. sclerotiorum* strains were co-determined by SsBV1, SsYkV1, and SsReV1. Although whether synergistic interaction among three mycoviruses exists in *S. sclerotiorum* still remains unresolved, we found that the accumulation of SsReV1 is significantly increased in *S. sclerotiorum* strains upon co-infections with SsBV1 and SsYkV1 (unpublished data). The SCH941 and its associated mycoviruses supply an excellent system for exploring the quadripartite interaction of fungi-virus-virus-plant.

Megabirnavirus Infects the Hypovirulent Strain SX466 With a Mitovirus and a Partitivirus

Strain SX466 harbors two dsRNA mycoviruses and an ssRNA mycovirus, including *Sclerotinia sclerotiorum megabirnavirus 1* (SsMBV1), SsMV2/SX466, and *Sclerotinia sclerotiorum partitivirus 2* (SsPV2/SX466) (Wang *et al.*, 2015). SsMBV1 forms rigid spherical particles with approximately 45 nm in diameter, and contains two dsRNA segments (dsRNA1 and dsRNA2) each of which possesses two ORFs (ORF1 & 2 on dsRNA1, ORF3 & 4 on dsRNA2). Interestingly, a papain-like protease domain in dsRNA2-encoded protein appears to have been obtained from the single-stranded RNA viruses via horizontal gene transfer events. dsRNA2/SsMBV1 is dispensable for SsMBV1 replication and packaging, but it could enhance transcript accumulation of dsRNA1/SsMBV1 and stability of SsMBV1 particle. This similar result was found in other megabirnaviruses infecting *R. necatrix*. Different from *Rosellinia necatrix megabirnavirus 1* (RnMBV1), SsMBV1 has a slight impact on fundamental biological characteristics of its host regardless of the presence or absence of dsRNA2/SsMBV1. Whether SsMV2/SX466 or SsPV2/SX466, or a combination of three mycoviruses is responsible for hypovirulence in strain SX466 needs to be further explored.

Strain Sunf-M is Coinfected With Two Unrelated dsRNA Mycoviruses

Although strain Sunf-M isolated from the diseased sunflower plant (*Helianthus annuus*) has strong virulence on its hosts, two mycoviruses, *Sclerotinia sclerotiorum nonsegmented virus L* (SsNsV-L) and *Sclerotinia sclerotiorum partitivirus S* (SsPV-S), and a dsRNA element were detected. SsNsV-L is 9124 nucleotides in length without a poly (A) tail. SsNsV-L has two large ORFs (ORF1 and ORF2) and ORF2 is predicted to encode RdRp. Genome comparison and evolutionary analysis suggested SsNsV-L represents a

novel viral evolutionary lineage. Two other strains (above 90% identities with SsNsV-L/Sunf) of SsNsV-L were detected from two strains of *Botrytis* spp.. SsPV-S in Sunf-M is a typical partitivirus based on the RdRp analysis, but its coat protein has the highest amino acid sequence similarity to IAA-leucine-resistant protein 2 (ILR2) of *Arabidopsis*, and its similarity to CPs of other partitiviruses is considerably lower. The systematic analysis further revealed that HGT may have widely occurred between dsRNA viruses and eukaryotic nuclear genomes but previously undetected. The similar result was obtained based on the analysis of Rosellinia necatrix partitivirus 2.

Mitoviruses Widely Exist in and Co-Infect *S. sclerotiorum*

Mitoviruses are usually considered to replicate and locate in mitochondria of fungi. Mitoviruses consist of a single ORF, as revealed by invoking fungal mitochondrial codon usage (UGA coding for tryptophan). Mitovirus encode RdRp, but lacking a protein capsid. Based on the NCBI database, thirty-four *Sclerotinia sclerotiorum* mitoviruses (SsMV) were temporarily named from SsMV1 (accession number JQ013377) to SsMV34 (accession number MF444264), which revealed that mitoviruses are highly prevalent and diverse in *S. sclerotiorum* relative to any other mycoviruses (Fig. 1). Moreover, multiple infection of a single isolate by mitoviruses is very common in fungi, including *S. sclerotiorum*. Two mitoviruses of SsMV1 and SsMV2 were found to co-infect the hypovirulent strain KL-1, and three mitoviruses including SsMV5, SsMV6, and SsMV7 co-infected the strain Lu471. In the following section, we only summarize mitoviruses from hypovirulent strains of *S. sclerotiorum*, and exclude mitoviruses detected via deep-sequencing.

Strain KL-1 was originally isolated from diseased lettuce in USA, and co-infected with two mitoviruses SsMV1 and SsMV2. The full-length cDNA of SsMV1/KL-1 and SsMV2/KL-1 has ~2500 nt, and usually has a lower GC content. Similar to reported mitoviruses, the UTRs of SsMV1/KL-1 and SsMV2/KL-1 have the stem-loop structures. SsMV1/KL-1 and SsMV2/KL-1 are considered to be the causal agents of hypovirulence in strain KL-1. Another strain (SsMV1/HCO25) of SsMV1 was characterized in a Chinese strain HCO25 isolated from the disease soybean. SsMV1/HCO25 shared the highest sequence identity (74%) with SsMV1/KL-1. The

Fig. 1 Maximum likelihood (ML) phylogenetic tree based on multiple alignments of full RdRp region of mitoviruses. Bootstrap values (%) obtained with 1000 replicates are indicated on the branches and only values more than 50 are shown. Branch lengths correspond to genetic distances; the scale bar (0.5) at the left corresponds to the genetic distance. A group of eight narnaviruses was an out-group. Mitovirus infecting *S. sclerotiorum* is indicated by blue typeface. GenBank accession numbers is followed in brackets.

UTRs of SsMV1/HC025 had an inverted complementarity, and could form a potentially stable panhandle structure, which lacks in SsMV1/KL-1. SsMV1/HC025 infection exerted obvious effects on host biological properties, including abnormal colony morphology, lower virulence, and the abnormal morphology of mitochondria.

SsMV2/16235 was detected in a hypovirulent strain 16235 isolated from an infected *Petroselinum crispum* (wild parsley) stem in New Zealand. SsMV2/16235 shares 91.6% amino acid sequence identity with RdRp of SsMV2/KL1, therefore being considered an isolate of SsMV2. A dsRNA profile suggested that at least three dsRNA segments appear in the strain infected by SsMV2/NZ1, and one of the three is the replicate form of SsMV2/16235, the other two segments are those of SsMV3/NZ1 and SsMV4/NZ1. Thus, *S. sclerotiorum* isolate 16235 was co-infected by a minimum of three different mitoviruses. The same research group detected mycoviruses from three *S. sclerotiorum* strains 14563, Lu471, and 11691 via a dsRNA extraction method. They initially dismissed that strain 14563 was co-infected by three mitoviruses (SsMV2/14563, SsMV5/14563, and SsMV6/14563), strain Lu471 harbors three mitoviruses (SsMV5/Lu471, SsMV6/Lu471, and SsMV7/Lu471), and strain 11691 contains SsMV5/11691 and an endornavirus (SsEV1). Shortly afterward, Illumina sequencing revealed more viruses in the same four fungal strains (16235, 14563, Lu471, and 11691): six mitoviruses in strain 16235; five mitoviruses and SsNSRV-1 in strain 14563; six mitoviruses, SsEV1 and SsNSRV-1 in strain Lu471; and five mitoviruses and two endornaviruses in strain 11691. These mycovirus detection patterns are more complex than previous detection patterns obtained with the dsRNA extraction method.

Three Strains of *S. sclerotiorum* Harbor Multiple Unassigned Mycoviruses or dsRNA Elements

Strain AX19 contains at least seven dsRNA segments (dsRNA1 to 7), and the known mycoviruses infecting strain AX19 include hypovirus (dsRNA2), ourmiavirus (dsRNA5), mitovirus (dsRNA6), and an unassigned virus of *Sclerotinia sclerotiorum* deltaflexivirus 1 (SsDFV1, dsRNA3). No information was obtained from the other dsRNA segments. The complete genome of SsDFV1 was predicted to contain a larger ORF and three smaller ORFs. Although a larger ORF encoded protein shares sequence similarities to the members within the order *Tymovirales*, SsDFV1 is markedly distant from all of the members in genomic organization and phylogenetic position. This fact has led the ICTV to create a family *Deltaflexiviridae* that accommodates SsDFV1. The second deltaflexivirus (SsDFV2) was isolated from hypovirulent strain 288 that was coinfecting by a botybirnavirus (BpRV1). SsDFV2 confers hypovirulence on its host and could break the limitation of host vegetative incompatibility to horizontal transmission, but the impact of SsDFV1 on *S. sclerotiorum* still need to be unexplored.

A new +ssRNA mycovirus designated as Hubei sclerotinia RNA virus 1 (HuSRV1) was discovered from the strain 277 of *S. sclerotiorum*. HuSRV1 is 4492 nt long and lacks a poly(A) tail. The genome size of HuSRV1 is smaller than most of mycoviruses except for mitoviruses, but four ORFs were predicted, and encode four putative proteins (protease, RdRp, coat protein, and hypothetical protein with unknown functions). HuSRV1 is placed in a phylogenetic branch distinct from known viruses. In addition, strain 277 was also infected by SsMTV1 that characterized in strain SZ-150, and its hypovirulent phenotypes was shown to be caused by HuSRV1 infection.

The Possible Reasons for the Co-Infections of Mycoviruses in *S. sclerotiorum*

The complex vegetative incompatibility does exist in *S. sclerotiorum* populations. It is usually considered that transmission of mycoviruses is limited by the vegetative incompatibility of host fungi. However, the majority of reported *S. sclerotiorum* strains were infected with multiple mycoviruses (Table 1). More mycoviruses that were not detected by traditional dsRNA extraction could be successfully and accurately detected or discovered by high throughput sequencing. A hypovirulent strain HC051 was confirmed to be co-infected by thirteen mycoviruses including DNA mycovirus, +ssRNA mycoviruses, -ssRNA mycoviruses, and dsRNA mycoviruses (unpublished data), suggesting that co-infections are more complex than we previously thought in *S. sclerotiorum*. Those phenomena also suggested that mycoviruses are likely to overcome the limitation of transmission caused by vegetative incompatibility under nature via some unknown mechanisms. Recently, Thapa and Roossinck (2019) summarized the determinants of co-infection of mycoviruses and how to break the limitation of vegetative incompatibility in filamentous fungi. In *S. sclerotiorum*, we herein list potential reasons for the co-infections of mycoviruses. (1) Some mycoviruses (Such as SsHADV1, SsPV1, and SsDFV2, etc.) are strong infectious. SsHADV1 virions could directly infect hyphae of *S. sclerotiorum* and easily transmit via hyphal contact. SsHADV1 is prevalent among *S. sclerotiorum* strains directly isolated from fields and infects a single strain with other unrelated mycoviruses. (2) Mycovirus (such as SsMYRV4) is capable of promoting horizontal transmission of heterologous mycoviruses between vegetatively incompatible strains. (3) Some mycoviruses act as RNA silence suppressors to resist an antiviral immune system of the host fungus. *S. sclerotiorum* could activate antiviral immune response (such as RNAi) upon mycovirus infections. On the contrary, mycoviruses also have evolved the mechanism to inhibit this host immune response. The satellite RNA of SsHV1 can inhibit the RNAi-related gene expression, therefore increasing the replication of its helper virus. (4) Mycoviruses are capable of escaping from the barrier of vegetative incompatibility system during infection of plants by the fungi hosting the viruses. The horizontal transmission rate of, for example, CHV1 in different vegetative compatible strains is significantly increased when fungal strains infect chestnut than when they grow on artificial medium. A similar phenomenon was found in *S. sclerotiorum* mycoviral transmission (unpublished data), suggesting that the mechanism of horizontal transmission under natural conditions is different from that under laboratory conditions, and remains to be further explored.

Glossary

Biological control A method to control pests and pathogens by using natural enemies.

Horizontal mycovirus transmission Transmission of viruses from infected to non-infected fungal strains via hyphal anastomosis.

Hyphal anastomosis Fusion of fungal hyphae. The formation of hyphal anastomoses allows cytoplasmic exchange and horizontal mycovirus transmission between different fungal strains.

Hypovirulence Reduced ability of a pathogen to cause disease. The term hypovirulence is commonly used in the

context of mycovirus-mediated attenuation of fungal virulence.

Transfection Artificially introducing viral particles or viral transcripts into fungal cells.

Vegetative incompatibility A genetic system that controls the ability of two fungal strains to form hyphal anastomoses and subsequently horizontal mycovirus transmission.

Vertical mycovirus transmission Transmission of viruses to sexual and asexual spores (progeny) produced by virus-infected fungal strains.

Introduction

Fungi represent a major group of pathogens that are able to infect plants and cause diseases in agricultural and forestry production systems. Management of plant diseases mainly depends on resistance breeding and chemical control with fungicides. However, fungal pathogens can overcome plant resistance and can develop tolerance against fungicides. In addition, chemical control can have undesirable side effects on the environment. Biological control offers an alternative disease management tool. Biological disease control utilizes natural enemies or parasites that attack and suppress pathogens. Viruses that infect fungi (so called mycoviruses or fungal viruses) have the potential to act as biological control agents against plant diseases. Mycoviruses have been found in all major groups of plant pathogenic fungi. However, in many cases they live inside the fungal host without causing it harm.

Fungal pathogens can also cause infections in humans and animals, including insects. Mycoviruses have been detected in several of these fungal pathogens. While some are associated with enhanced fungal virulence, others can induce hypovirulence or debilitation in their hosts. This article, however, will focus on mycoviruses that occur in plant pathogenic fungi alone and will not discuss those present in other fungal pathogens.

Disease Cycle of Plant Pathogenic Fungi

Plant pathogenic fungi can have complex life cycles. The disease process typically begins by an initial infection from fungal spores that germinate on, then penetrate into the host plant. This is followed by parasitic growth inside the host tissue. Depending on the type of tissue attacked and the severity of the infection, parts of the plants (e.g., for leaf pathogens) or the entire plant (e.g., for root or stem pathogens) are killed by the pathogens. Finally, the fungal pathogens produce spores on the infected plant tissue. These spores are then dispersed to new hosts by wind, rain, or insect vectors. Many fungal pathogens can reproduce both sexually and asexually. Sexual reproduction takes place after mating of two individuals, which upon meiosis produce genetically recombinant sexual spores. In contrast, asexual spores are produced by single individuals and are all genetically identical. Asexual fungal spores can have two functions. They can cause new infections, but can also act as spermatia during sexual reproduction.

Two main lifestyles are distinguished in plant pathogenic fungi. Biotrophic pathogens derive nutrients from living plant cells, therefore hosts are not killed rapidly. In contrast, necrotrophic pathogens derive nutrients from dead cells that have been killed by the pathogen. Necrotrophic pathogens usually attack weak or damaged plants and can also survive as saprophytes on dead plant tissues.

Basic Concepts for Mycovirus-Mediated Biological Control

For a mycovirus to act as biological control agent, four basic criteria must be fulfilled:

- (1) It must reduce the virulence of the pathogen (i.e., cause hypovirulence) by suppressing at least one phase in the disease cycle of the fungal pathogen. Both the infection or the reproduction process of the pathogen can be targeted. Suppressing either process alone, or in combination will disturb the disease epidemic and reduce the severity of the disease.

- (2) The mycovirus must be transmissible into the fungal pathogen that is causing the disease. Most mycoviruses do not have an extracellular phase. Meaning that they can only be transmitted upon hyphal anastomosis (fusion) and cytoplasmic exchange between fungal individuals. Extracellular transmission of virus particles can also occur, but this seems to be an exception.
- (3) It must be able to overcome the cellular defense mechanisms induced by fungi against virus infections. Fungi use RNA silencing as an antiviral defense pathway. Viral RNA within the fungal host is recognized and broken-down into small RNA fragments. Some mycoviruses can overcome this defense response by suppressing the RNA silencing pathway.
- (4) Finally, the mycovirus must be able to replicate and spread through the fungal mycelia. Most fungi produce networks of filamentous hyphae with actively growing hyphae at the edge of the thallus. Fungal reproductive structures (i.e., fruiting bodies) develop in the older growths. Spread of the virus into actively growing hyphae is important to interfere with mycelial growth and the infection process, as well as to allow for horizontal virus transmission. While spread of the mycovirus into the reproductive structures is required for vertical virus transmission into spores.

Further desired characteristics include the spread and persistence of the biocontrol mycovirus in the pathogen population. Since most mycoviruses do not have an extracellular phase they are fully dependent on their host for their survival and spread. This means the mycovirus can only spread together with its fungal host, which typically disseminates by spores. Consequently, the spread of a mycovirus depends on vertical virus transmission into fungal spores.

General Procedure for Developing a Mycovirus-Mediated Biological Control System

Virus Detection and Characterization

The detection of mycoviruses is the first step towards the development of a biological control system. Isolates of known pathogenic species, which exhibit slow or debilitated growth *in vitro* and/or reduced virulence *in planta* are particularly interesting for virus screening. For necrotrophic pathogens, mycoviruses that cause hypovirulence are more likely detected among fungal isolates recovered from the saprophytic stage of the fungus.

The classical approach for the detection of mycoviruses involves the extraction of double-stranded (ds) RNA from the fungal isolates. This approach exploits the fact that most mycoviruses are RNA viruses that either have a dsRNA genome, or in the case of single-stranded RNA viruses, a dsRNA replicative form. Further detection steps include: synthesis of complementary DNA (cDNA) using reverse transcriptase and sequencing, or cloning of the cDNA fragments into appropriate vectors and sequencing. The alignment of overlapping cDNA clones then allows the assembly of the viral genome. This approach was first used in the 1990s by Donald Nuss and co-workers to determine the complete nucleotide sequence of the *Cryphonectria hypovirus 1* (CHV1) genome, one of the most well-characterized and well-known biocontrol mycoviruses (Table 1).

In recent years, many novel mycoviruses have been detected by using next-generation sequencing, also known as ‘high-throughput’ or ‘deep sequencing’. This detection approach has co-opted RNA-Seq (RNA sequencing) tools that were originally developed for whole transcriptome analysis. The procedure starts with the extraction of total RNA from a fungal isolate, followed by synthesizing and then sequencing the total cDNA. Putative viral sequences are then quality controlled using bioinformatic tools and then identified with BLAST (Basic Local Alignment Search Tool) searches using viral sequence collections. In the most successful searches, a match can be found with conserved motifs in viral genes encoding the RNA-dependent RNA polymerase. These RNA polymerases are responsible for the replication of the viral genomes. The viral RNA polymerase gene is also the first choice for phylogenetic analysis to reveal the taxonomic classification of the detected mycovirus.

Once the nucleotide sequence of a mycovirus has been determined, specific PCR assays can be designed to screen fungal culture collection for the presence of a particular mycovirus. The availability of a large culture collection is important because different fungal isolates can host different virus strains, which often vary in their phenotypic effects on its host. Thus, the potential to explore mycovirus diversity could be crucial for finding suitable biological control agents.

Testing for Phenotypic Effects of the Mycovirus

As outlined earlier, it is essential that a mycovirus has a negative effect on its fungal host to be considered as a biocontrol agent. To confirm a negative mycoviral effect, pairs of isogenic fungal strains that differ only in presence/absence of the particular mycovirus are required. Such pairs can be obtained by: (1) horizontal virus transmission from a virus-infected to a virus-free strain by co-culturing and hyphal fusion (anastomosis) or protoplast fusion; (2) elimination of the mycovirus from an infected strain by using antiviral chemicals (e.g., ribavirin), thermal treatments, or single spore isolations; (3) *in vitro* transfection of protoplasts of a virus-free strain with virus particles or infectious viral transcripts derived from a cDNA clone; or (4) transfection of protoplasts of a virus-free strain with an infectious cDNA clone. Phenotypes that should then be tested must include those related to growth and sporulation on artificial agar medium, as well as *in planta*. Poor or debilitated growth of virus-infected strains on agar medium is, in most cases, a reliable indicator for reduced growth (virulence) *in planta*. The virus effect can be quantified as the difference between the performance (e.g., growth rate, lesion area) of the virus-infected and that of the corresponding isogenic virus-free strain. This should be expressed as a proportion (%) of the performance of the virus-free strain. A negative virus effect therefore results in a negative proportion value.

Table 1 Examples of proven and potential mycovirus-mediated biological control of plant diseases

<i>Fungal pathogen</i>	<i>Mycovirus (Family)</i>	<i>Phenotypic effects on fungal host beside hypovirulence</i>	<i>Transmission properties</i>	<i>Biocontrol experience</i>
<i>Cryphonectria parasitica</i> Necrotrophic bark pathogen causing chestnut blight on <i>Castanea</i> species	CHV1 <i>Cryphonectria hypovirus 1 (Hypoviridae)</i>	Reduced sporulation and pigmentation, female sterility	Horizontal transmission via hyphal contacts, vertical transmission into asexual spores, no transmission into sexual spores	Main method of control of chestnut blight in European orchards and forests: Therapeutic treatments and natural dissemination of hypovirulence, field experiments in North America
	CHV2 <i>Cryphonectria hypovirus 2 (Hypoviridae)</i>	Moderately reduced fungal sporulation and pigmentation	Horizontal transmission via hyphal contacts, scarcely transmitted into asexual spores, no transmission in sexual spores	Laboratory experiments
	CHV3 <i>Cryphonectria hypovirus 3 (Hypoviridae)</i>	Slow growth in culture	Horizontal transmission via hyphal contacts, scarcely transmitted into asexual spores	Therapeutic treatments of chestnut blight cankers in the US
	MyRV1 <i>Mycoreovirus 1 (Reoviridae)</i>	Altered culture morphology	Infectious as virus particles in transfection assays	Laboratory experiments
	CpMV1 <i>Cryphonectria parasitica mitovirus 1 (Narnaviridae)</i>	Mildly reduced mycelial growth	Horizontal transmission via hyphal contacts, vertical transmission into conidia, maternal inheritance in sexual crosses	Laboratory experiments using excised chestnut wood and bark
<i>Ophiostoma novo-ulmi</i> Wilt pathogen causing Dutch elm disease	OnuMV <i>Ophiostoma novo-ulmi mitoviruses (Narnaviridae)</i>	Debilitated growth, reduced conidial viability, mitochondrial malfunction	Horizontal transmission by hyphal contacts, Vertical transmission into conidia	Inoculations studies with elm trees
<i>Sclerotinia sclerotiorum</i> Necrotrophic pathogen causing white mold or stem rot on many plant species	SsHADV1 <i>Sclerotinia sclerotiorum hypovirulence-associated DNA virus 1 (Genomoviridae)</i>	Abnormal culture morphology, reduced sclerotia size	Horizontal transmission via hyphal contacts, extracellular transmission of virus particles	Preventive application, growth chamber experiments and field trials
	SsPV1 <i>(Sclerotinia sclerotiorum partitivirus 1 (Partitiviridae))</i>	Reduced mycelial growth, reduced sclerotia production	Horizontal transmission via hyphal contacts, transmission into sclerotia, interspecific transmission to other <i>Sclerotinia</i> species.	Laboratory experiments
	SsMV1 <i>Sclerotinia sclerotiorum mitovirus 1 (Narnaviridae)</i>	Reduced mycelial growth, mitochondrial malformation	Horizontal transmission via hyphal contacts	Laboratory experiments with detached leaves
	SsHV2 <i>Sclerotinia sclerotiorum hypovirus 2 (Hypoviridae)</i>	Reduced mycelial growth	Not known	Laboratory experiments with detached leaves
<i>Botrytis cinerea</i> Necrotrophic pathogen causing	BcMV1 <i>Botrytis cinerea mitovirus 1 (Narnaviridae)</i>	Slow mycelial growth, abnormal mycelial sectors, decreased formation of infection cushions	Horizontal transmission via hyphal contacts, vertical transmission to asexual conidia	Laboratory experiments with detached leaves

white mold or stem rot on many plant species	BcRV1 <i>Botrytis cinerea</i> RNA virus 1 (eventually new family)	Reduced mycelial growth, sectorized colony margin	Horizontal transmission via hyphal contacts, vertical transmission to macroconidia	Laboratory experiments with detached leaves
	BcHV1 <i>Botrytis cinerea</i> hypovirus 1 (<i>Hypoviridae</i>)	Decreased formation of infection cushions	Horizontal transmission via hyphal contacts	Laboratory experiments with detached leaves
	BcPV2 <i>Botrytis cinerea</i> partitivirus 2 (<i>Partitiviridae</i>)	Changed culture pigmentation, reduced production of conidia and sclerotia	Horizontal transmission via hyphal contacts	Laboratory experiments with detached leaves
	Bc378V1 <i>Botrytis cinerea</i> CCg378 virus 1 (<i>Partitiviridae</i>)	Reduction of sporulation and laccase activity	Not known	Laboratory experiments with detached leaves
<i>Rosellinia necatrix</i> Necrotrophic pathogen causing root rot in many woody plant species	RnMBV1 <i>Rosellinia necatrix</i> megabirnavirus 1 (<i>Megabirnaviridae</i>)	Reduced mycelial growth	Infectious as virus particles in transfection assays	Greenhouse experiments with apple seedlings
	MyRV3 <i>Mycoreovirus</i> 3 (<i>Reoviridae</i>)	Reduced mycelial growth	Infectious as virus particles in transfection assays	Greenhouse experiments with apple seedlings
<i>Helminthosporium victoriae</i> Necrotrophic pathogen causing Victoria blight of oats	HvV190S <i>Helminthosporium victoriae</i> virus 190S (<i>Totiviridae</i>)	Reduced growth, production of abundant white aerial mycelium, excessive sectoring	Not known, transfection of <i>C. parasitica</i> possible and resulting in a hypovirulent phenotype	Laboratory experiments with apples and branches
<i>Fusarium graminearum</i> Necrotrophic pathogen causing Fusarium head blight of wheat, barley and other small-grain cereals	FgV1 <i>Fusarium graminearum</i> virus 1 (<i>Fusariviridae</i>)	Reduced mycelial growth rate, increased pigmentation, inhibition of mycotoxin production	Horizontal transmission via hyphal contact, vertical transmission to conidia	Laboratory experiments
	FgV-ch9 <i>Fusarium graminearum</i> mycovirus China 9 (<i>Chrysoviridae</i>)	Reduced mycelial growth rate and sporulation, abnormal colony morphology, disorganized cytoplasm	Vertical transmission to conidia	Laboratory and greenhouse experiments
	FgHV2 <i>Fusarium graminearum</i> hypovirus 2 (<i>Hypoviridae</i>)	Reduced mycelial growth rate, conidiation and mycotoxin production	Not known	Laboratory experiments with wheat spikes

Transmission Properties

To be able to exploit a mycovirus's biocontrol ability, a mycovirus needs to be capable of infecting the target pathogen. Since the vast majority of mycoviruses have no extracellular phase, virus infection only occurs upon hyphal fusion between infected and non-infected fungal individuals. Horizontal virus transmission abilities can be tested for on agar medium by co-culturing (pairing) virus-infected and virus-free strains. Mycovirus transmission can be directly observed in the recipient strain in some instances, when the recipient strain adopts the cultural characteristics of the virus donor strain. For example, CHV1 suppresses pigmentation in the chestnut blight fungus, *Cryphonectria parasitica*. Infected fungal isolates exhibit a white culture morphology, compared to orange pigmented virus-free isolates. Horizontal transmission of CHV1 can be followed by observing the change in pigmentation in the virus-free isolate. However, culture morphology is not always a reliable indicator for virus infection. Successful virus transmission must be confirmed by a virus-specific PCR assay or dsRNA extraction. Failure of horizontal mycovirus transmission is often due to vegetative incompatibility (see Glossary) between individuals of the same fungal species. This non-self-recognition system restricts the formation of hyphal anastomoses and consequently the horizontal transmission of mycoviruses.

To be able to spread and persist in a natural environment, the mycovirus needs to be dispersed through the spores of its fungal host. Confirmation of vertical virus transmission into spores requires single-spore cultures derived from a virus-infected isolate. The cultures are then tested for the presence of the mycovirus following the same methodology as horizontal transfer tests. For most mycoviruses, vertical transmission into asexual spores (conidia) is relatively easy to assess because conidia are often formed on agar medium. Transmission into sexual spores is more difficult to assess. In heterothallic fungal species, mating between two sexually compatible fungal isolates is needed for the production of sexual fruiting bodies. For vertical transmission studies, at least one of the two mating partners should be mycovirus-infected. In homothallic species, self-fertilization occurs in a single isolate which produces sexual fruiting bodies without mating type partner. Sexual fruiting bodies may be produced in the laboratory under controlled conditions using defined fungal strains. Alternatively, for highly prevalent mycoviruses, fruiting bodies or sexual spores can be collected in the field and single spore cultures analyzed in the laboratory.

Biocontrol Testing in the Field

Once a mycovirus has been shown to cause transmissible hypovirulence under laboratory and greenhouse conditions, further testing of its biocontrol potential should be conducted in the field. For most applications, a mycovirus-infected fungal strain is used. The mycovirus acts as the biological control agent and the fungal strain is a necessary carrier of the mycovirus. Strain-specific identification of both fungal carrier and mycovirus is important for tracing these organisms after field applications and determining their efficiency and persistence. Traceability markers are based on intra-specific genetic variations and include microsatellite markers for fungal strains and single nucleotide polymorphisms (SNPs) for mycovirus strains. Field trials should also demonstrate the efficacy of the biological control, i.e., a reduction in disease severity and an increase in plant productivity.

Biosafety Issues

Any release of a fungal carrier strain and a mycovirus into the environment requires consideration of biosafety issues. Critical areas of concern include human health (worker and consumer risk) and risk for non-target organisms (e.g., bees, beneficial fungi). In respect to the fungal carrier, the potential production of toxins/secondary metabolites needs to be considered. Such components may not only harm non-target organisms in the field, but could also affect groundwater quality.

Molecular Approaches to Improve the Use of Mycoviruses as Biological Control Agents

Studies in the *Cryphonectria*-hypovirus system have outlined strategies to improve mycovirus-mediated biocontrol using molecular approaches. Spread of the hypoviruses in this system is limited by the fungal vegetative incompatibility system and by exclusion of the virus during sexual reproduction of the fungus. To overcome these limitations, *C. parasitica* strains have been genetically engineered by integrating an infectious cDNA copy of the virus into the fungal genome. In sexual crosses with these strains, half of the progeny (regardless of their vc types) will receive the infectious cDNA copy and become virus-infected. Another promising approach involves gene disruptions at multiple *vic* loci in *C. parasitica* resulting in super donor strains. These strains exhibit enhanced ability to transmit the virus into *C. parasitica* populations with high vc type diversity. The potential to extend the natural host range of mycoviruses was also demonstrated with CHV1, which was introduced as synthetic transcripts into related fungal species.

Selected Examples for Mycovirus-Mediated Biological Control

Mycoviruses that induce hypovirulence may have the potential to be used as biological control agents for several plant pathogenic fungi (Table 1). Hypovirulence in the chestnut blight fungus represents the best-known biocontrol system and will be covered in this section along with other well-known examples.

Hypovirulence in *Cryphonectria parasitica*

The “exclusive transmissible hypovirulence”

Chestnut blight, caused by the ascomycete fungus *Cryphonectria parasitica* (Murr.) Barr., is probably the most well-known example of a tree disease successfully controlled via mycovirus-mediated hypovirulence. Main hosts of this pathogen are species in the genus *Castanea* (family *Fagaceae*), on which the fungus causes perennial bark lesions (so-called ‘cankers’) on stems and branches, eventually leading to wilting of the plant parts distal to the infection point. The fungus originates from Eastern Asia (China, Japan, and Korea) and was accidentally introduced in the 20th century to North America and Europe. In the new continents *C. parasitica* encountered two susceptible chestnut species *Castanea dentata* (Marsh.) Borkh. (American chestnut) and *C. sativa* Mill. (European chestnut).

In North America, the chestnut blight epidemics resulted in the ecological extinction of the formerly forest forming *C. dentata* within its native distribution of 3.6 million hectares. In Europe, after an initial virulent phase of the epidemics that caused high tree mortality, chestnut trees showing atypical superficial, non-lethal bark cankers were observed in Italy and in France. The *C. parasitica* strains isolated from these cankers presented a different phenotype than those recovered from virulent cankers. Specifically, instead of showing an orange pigmentation and a strong sporulation on potato dextrose agar (PDA), they were white and did not sporulate. The atypical strains were reduced in virulence when inoculated on chestnut trees. Further analyses revealed that this phenomenon, which was then called hypovirulence, was associated with the presence of dsRNA in the *C. parasitica* mycelium.

This dsRNA represents the replicative form of a mycovirus in the family *Hypoviridae*, namely *Cryphonectria hypovirus* 1 (CHV1). Hypoviruses are positive-stranded RNA viruses, located in the cytoplasm of the fungal host. Aside from CHV1, the genus *Hypovirus* includes three other well-characterized species: *Cryphonectria hypovirus* 2, *Cryphonectria hypovirus* 3, and *Cryphonectria hypovirus* 4. The exemplar strains of these species, *Cryphonectria hypovirus* 2 (CHV2), CHV3 and CHV4, are phylogenetically related to CHV1, but have different effects on the fungal host. CHV2 and CHV3 also induce a hypovirulent phenotype in *C. parasitica*, whereas the presence of CHV4 does not cause hypovirulence in *C. parasitica*. In North America, CHV3 and CHV4 are the most common hypoviruses, but CHV2 also occurs. In Asia, both CHV1 and CHV2 are present. In Europe, CHV1 is the only hypovirus reported to be present.

CHV1 inhibits *C. parasitica*'s sexual reproduction, strongly reduces asexual sporulation, and attenuates parasitic growth of its fungal host. Hypovirulent *C. parasitica* strains are not able to colonize and kill the cambium of *C. sativa*. As a result, the plant part distal to the infection point survives. Vertical transmission of CHV1 is restricted to asexual spores (conidia) and occurs at variable frequencies. In contrast, sexual spores (ascospores) only spread the virulent form of the pathogen. Horizontal CHV1 transmission to other fungal mycelia via hyphal anastomosis also occurs and is controlled by a vegetative compatibility (vc) system (Fig. 1), involving at least six unlinked, di-allelic vegetative incompatibility (*vic*) loci. Transmission success is highest between vegetatively compatible *C. parasitica* strains, meaning strains that have the same alleles at all *vic* loci. Transmission is severely reduced if strains are heteroallelic (i.e., have different alleles) at five of the six *vic* loci. The sixth locus, *vic4*, does not seem to affect CHV1 transmission. The other five *vic* loci restrict CHV1 transmission in a variable way. In most cases, restriction is asymmetric depending on which *vic* allele is present in the CHV1 donor or recipient strain. Field investigations showed that vc barriers seem to be less restrictive in the field than estimated from in vitro studies. Allelic combinations at the six *vic* loci define a total of 64 *vic* genotypes which correspond to the 64 vc types (EU-1 to EU-64) genetically characterized so far. However, the presence of vc types not compatible with these 64 described types suggest that vegetative compatibility in *C. parasitica* is most likely regulated by more than six *vic* loci or that additional alleles exist at the known *vic* loci.

CHV1 infected strains exhibit a white culture morphology, which enables the visual assessment of hypovirus transmission. Photos: Phytopathology, WSL.

Several genetically distinct subtypes of CHV1 have been identified in Europe, whose geographic distribution reflects the invasion history of *C. parasitica*. Moreover, several recombination events seem to have contributed to the evolution of CHV1 in Europe. The Italian subtype (subtype I) is the most widespread in central and south-eastern Europe (Italy, Switzerland, south-eastern France, Bosnia-Herzegovina, Croatia, Slovenia, Macedonia, Greece and Turkey). This subtype is represented by the two well characterized strains CHV1/Euro7 and CHV1/EP721. The prototypic hypovirus CHV1 (CHV1/EP713) belongs to the subtype F1. The CHV1 subtype F1 has been found in France and Spain together with subtypes F2, and D/E. In Eurasian Georgia a unique subtype (G) occurs that displays a recombinant pattern between subtypes F2 and D/E. The different subtypes vary in their virulence toward the infected *C. parasitica* strains. Specifically, subtype I has a mild effect on fungal virulence and sporulation and is commonly associated with a high natural prevalence of hypovirulence. In contrast, subtypes F1 and F2 have a severe effect on their fungal host and almost completely inhibit its parasitic growth and sporulation.

Artificial application of hypovirulence

As early as 1965, the field application of hypovirulent strains of *C. parasitica* for biocontrol of chestnut blight was proposed by the French mycologist Jean Grente. In the 1970s in south-eastern France, the hypotheses that the “exclusive transmissible hypovirulence” can be transmitted in the field through inoculations of cankers, as well as that the natural spread of hypovirulence observed in Italy in the 1950s can be accelerated by human intervention, were tested. To this end, virulent cankers were inoculated with hypovirulent *C. parasitica* strains (Fig. 2). Inoculated cankers healed following treatment and hypovirulent strains were isolated from cankers on surrounding trees. Following these first promising results, the French Ministry of Agriculture promoted biological control to help mitigate chestnut blight in France. By 1976, all French orchards had benefited from artificial treatments. Before any field application, the *vc* types present in the designated orchard or stand had to be determined. The necessary canker sampling was organized by INRA (French National Institute for Agricultural Research) in orchards and adjacent coppices. Technical facilities were also provided by INRA to grow and distribute hypovirulent strains. The following biocontrol treatment consisted of stripping the edges of the cankers, making holes with a cork borer in healthy bark tissue around the margins, and filling the holes with a mixture containing one or more hypovirulent strains (in case of different *vc* types). Mixtures were adapted to each production area. From 1998 on, private companies have started to market the hypovirulent strains in France. A license of know-how was established by INRA with these companies in order to control the quality of the product and to be sure that the hypovirulent strains sold are best appropriated for the French *C. parasitica* populations. After 20 years of biological control, in 1995, a new research program on chestnut blight was initiated at INRA in Bordeaux. This program, carried out in close collaboration with several organizations, has allowed to redefine the mixtures of hypovirulent strains to be used, to develop a new method of application of the product, and to characterize the different viral strains and their transmission properties. Chestnut blight is currently well controlled in southern France. Although its incidence in orchards and coppices is still high, chestnut growers no longer consider it a major problem, except for young grafted trees.

In Greece, artificial hypovirulence has also been intensively applied for the biological control of chestnut blight. In 1995, an initial project was started to determine the diversity and distribution of *C. parasitica* *vc* types. Following this (1998–2000), a pilot biocontrol project was carried out in the chestnut coppice stands of Mt. Athos. Roughly 20'000 virulent cankers were treated with a hypovirulent strain of *vc* type EU-12. Promising results from this pilot project led to two nationwide treatment campaigns (2007–2009 and 2014–2016). It is estimated that roughly 170,000 cankers were treated with a CHV1 strain (subtype I), which was naturally present at Mt. Athos. The hypovirulent inoculum was prepared at the Forest Research Institute in Vassilika on a commercial level. In counties where more than one *vc* type were found, a mixture of inoculum of the corresponding *vc* types was applied, as done in France. To help forest managers in organizing the artificial introduction of hypovirulence in areas without naturally occurring hypovirulence, an Integrated Biological Control Plan was developed. Evaluations after the treatment campaigns showed that the treated cankers had healed and the released CHV1 strains had started to naturally infect, and heal, non-inoculated cankers. The type of forest management strongly influenced the spread of the hypovirus, which was faster in coppice forests than in

orchards. Thanks to the successful treatments, Greek forest managers and chestnut growers are currently much less concerned about chestnut blight than 20 years ago and chestnut cultivation has re-gained importance.

Artificial canker treatments with hypovirulent *C. parasitica* strains have also been conducted for more than 20 years in Northern Switzerland. In contrast to Southern Switzerland, no natural hypovirulence has appeared North of the Alps. At roughly 20 sites, more than 2'000 cankers were treated with a local *C. parasitica* isolate of the dominant vc type that was converted with a CHV1 infected isolate from Southern Switzerland. Following the method adopted in France, holes were applied around the virulent cankers and filled with the hypovirulent inoculum. One to two years after treatment, canker morphology was assessed and *C. parasitica* was re-isolated from both treated and untreated cankers. Results revealed the presence of the released CHV1 strain in most treated cankers, which had consequently healed. This confirmed the effectiveness of therapeutic canker treatment in Switzerland. However, there were considerable differences among sites in the spread of the hypovirus to untreated cankers. Although factors determining these differences are still unclear, it seems that the incidence of canker treatment may play an important role. Specifically, a threshold number of cankers must be treated before CHV1 begins to spread into the local *C. parasitica* population.

In North America, natural hypovirulence is associated with the hypovirus CHV3. This has occurred in a few chestnut stands in Michigan and Ontario, which are outside the natural range of the American chestnut. Artificial application of hypovirulence for biological control of chestnut blight in forests and plantations started as early as the mid-1970s in West Virginia, Connecticut, Virginia and Wisconsin. However, results were much less positive than in Europe. Although therapeutic canker treatment has been mostly successful, hypovirulence has largely failed at the population level, meaning that the released hypoviruses did not spread in the local *C. parasitica* populations. Two of the most significant factors responsible for this failure are thought to be the high susceptibility of American chestnut to *C. parasitica* and local vc type diversity which is much higher than in Europe. Molecular approaches have been recently used to enhance the establishment and dissemination of the hypovirus. These include the production of transgenic *C. parasitica* strains carrying an infectious cDNA copy of CHV1 that is integrated into the fungal genome. As well as the production of super hypovirus donor strains, which are able to transmit the hypovirus to recipient strains that are heteroallelic at one-to-five *vic* loci. In a recent field trial in the US, the use of the super donor strains resulted in enhanced hypovirus transmission into treated chestnut blight cankers. This result highlights the potential of these strains to serve as universal hypovirus carriers for biological control of *C. parasitica*, particularly for populations with high vc type diversity.

Therapeutic treatment of individual *C. parasitica* cankers on *C. sativa* and *C. dentata* has been mostly successful and provides an efficient control method for these perennial infections. In contrast, mycovirus-mediated hypovirulence has frequently shown less success at the population level, especially in North America. Natural hypovirulence is still a recent phenomenon in Europe and its success is strongly dependent on characteristics of the three actors involved in this pathosystem, i.e., virus, fungus, and tree. The outcome of the interaction is also affected by the environment. Therefore, predicting the sustainability of this natural biological control system is particularly difficult.

Mycoviruses other than hypoviruses have also been detected in *C. parasitica*. Among these viruses, two mycoreovirus strains and one mitovirus strain can also induce a hypovirulent phenotype. *C. parasitica* isolates infected by either of two mycoreovirus strains (MyRV1 or MyRV2) exhibit a strong hypovirulent phenotype. Both mycoreoviruses are infectious as particles in transfection assays allowing to transfer the virus to fungal isolates in different vc types. The mitovirus strain, CpMV1/NB631, has a mild effect on its host. CpMV1 is transmitted at high frequency into asexual spores and, as expected for a mitochondrial mycovirus is maternally inherited.

Hypovirulence in *Ophiostoma novo-ulmi*
